**Cupriethylenediamine Cellulose Solvent: Nature.** R. M. Levy and P. Muffat. *Paper Trade J.*, 1944, 118, *TAPPI*, 40-44. Previous work on the nature of cupriethylenediamine and its reactions with cellulose are reviewed, and an account is given of spectrophotometric and electrometric studies, the preparation and examination of solid cupriethylenediamine complexes, and a study of the reaction of the diamine with cellulose. The results lead to the following conclusions: (1) The dissolution of cellulose in cupri-amine bases is due to the formation of a complex copper-cellulose anion. (2) The active component responsible for the dissolution of cellulose in copper-saturated cupriethylenediamine is most probably the dimeric compound  $[\text{Cu en}_2][\text{Cu}(\text{OH})_2]$ , or some similar solvated compound. (3) The active components responsible for the dissolution of cellulose in the copper-diamine solution containing a large excess of ethylenediamine may be  $(\text{Cu en}_3)(\text{OH})_2$  and  $\text{Cu}(\text{OH})_2$ . The similarity of the blue colour of the two active diamine solvents indicates, at least superficially, that some form of cupric hydroxide may be responsible for the cellulose-complex formation, and hence its dissolution. This is in accord with the nature of the compounds proposed. The blue-violet cupri-di-ethylenediamine compound is not a solvent for cellulose. (4) The ratio of total diamine to total copper in saturated solutions is probably less than 2:1, which indicates that both the cupri-mono-amine and cupri-di-amine are present. This ratio and the equilibrium between the mono- and di-compounds are dependent on concentration, and until more refined methods of analyses are made available the exact nature of these ratios and equilibrium constants cannot be accurately determined. (5) The cupriethylenediamine and cupraammonium systems may be considered similar in all respects except in the stability of the two complexes. (6) Copper appears to retain a coordination number of 4 in its complex formations, but it appears probable that an additional two groups may be added to the complex in the form of loosely bound constituents, similar to water of crystallisation, giving copper an apparent coordination number of 6. C.

**Nitrocellulose Fractions: Sedimentation and Molecular Weight.** H. Mosimann. *Helv. Chim. Acta*, 1943, 26, 369-398 (through *Chem. Abstr.*, 1943, 37, 6522<sup>a</sup>). A new sedimentation cell of synthetic resin (Tufnol) mounted in a metal cylinder is described. Instead of using a blanketing liquid layer to minimize solvent evaporation the author closed the cell with a screw and the fact that the quartz windows were only 18 mm. in diameter decreased the danger of their breaking. Although equilibrium was apparently attained in 4 days, all tests were continued for a total of 6 days. The nitrocellulose fractions described in a previous paper were studied. Correct values of molecular weight,  $M$ , are obtained only in dilute solutions where  $M$  is independent of concentration, centrifugal field and solvent. Nitrocellulose fractions having  $M$  over 80,000 deviated in behaviour at the lowest concentrations that could be tested. One

fraction, which revealed more than one maximum in the velocity centrifuge, gave decidedly anomalous results because part of the material actually sedimented to the bottom of the cell in the equilibrium run. Except perhaps at low values of  $M$ , viscometric molecular weights were not linearly related to  $M$ , but gave a curve convex to the  $M$  axis. C.

**Starch: Crystallisation from Solvent Mixtures.** E. Wiegel. *Kolloid Z.*, 1943, 102, 145-154 (through *Chem. Abstr.*, 1943, 37, 6926<sup>9</sup>). Optimum concentration of ethyl alcohol for crystallisation of starch was 30-35 per cent. Other solvents used included butyl alcohol, isobutyl alcohol and isopropyl alcohol. Photo-micrographs and X-ray diagrams are shown (in the original paper). On freezing concentrated solutions, a filamentous form which went over to an amorphous form was obtained. C.

**Ozone: Adsorption by Silica Gel, Alumina Gel and Cotton.** E. Briner and A. Lachmann. *Helv. Chim. Acta*, 1943, 26, 346-357 (through *Chem. Abstr.*, 1943, 37, 6532<sup>11</sup>). In experiments at 0, 100, 200 and 400° with mixtures of sulphur dioxide and oxygen in contact with partially dehydrated silica gel very little sulphur trioxide was formed. Whilst the addition of ozone to the gas mixture greatly increased sulphur trioxide formation, the oxygen fixed was only 10-20 per cent. of that contributed by the ozone; an optimum was found at 200° C. Thus the use of ozone together with silica gel has little value for sulphuric acid manufacture. The reaction probably proceeds through formation of sulphurous acid on the gel and subsequent oxidation, accelerated by ozone to sulphuric acid. Direct oxidation of sulphur dioxide by ozone is believed not to take place, for when a mixture of these gases is adsorbed on the gel at low temperatures, the blue-violet colour characteristic of ozone persists. Adsorption of ozone on silica gel increased greatly as the temperature decreased from 0° to -80°; at the same time the proportion of ozone decomposed decreased. Alumina gel gave nearly the same magnitude of ozone adsorption and decomposition. Absorbent cotton also adsorbs ozone about as well as the gels, but decomposes it less, which explains the persistence of ozone odour on cotton. C.

**Liquids: Wetting and Spreading.** L. J. Bircher. *J. Chem. Education*, 1943, 20, 428-430 (through *Chem. Abstr.*, 1943, 37, 6517<sup>7</sup>). One liquid will wet a second liquid only if the work of adhesion of the former for the latter exceeds the work of cohesion holding the molecules of the former in a drop. This theory is demonstrated in a laboratory experiment by determining surface tension of solutions containing different molecular ratios of caustic soda and lauric acid, and by determining interfacial tensions of each of these solutions against a drop of paraffin oil. A solution of a wetting agent is also studied. C.

**Surface Tension Dynamometer: Wall Effect.** F. de Block and J. Mattheeuws. *Wis-Natuurkund. Tijdschr.*, 1940, 10, 22-27 (through *Chem. Zentr.*, 1941, 1, 2938-2940 and *Chem. Abstr.*, 1943, 37, 6510<sup>9</sup>). Comparative measurements of surface tension by the rupture method, the height-of-rise method, and the drop-weight method are discussed together with the possible reasons for variations in results. In order to study the effect of the material in the rupture method, tests were made with cylinders of various materials including stainless steel, "staybrite" steel, Zn, Mg, Al, a hard Al-Cu alloy, Cu, and Ni-, Au- and Pt-plated Cu. In determinations of the surface tension of water, carbon tetrachloride, heptane and acetone the deviations found were sometimes 10-20 times as great as the observed error. The deviations were certainly due in part to the nature of the metal, probably also to the different physical and chemical behaviour of the liquids investigated, polar effects at the cylinder wall, the microscopic form of the edge or the type of mechanical treatment to which the material had been subjected. Investigations of these factors are in progress. C.

**Fibres: Genesis.** W. Ostwald. *Kolloid Z.*, 1943, 102, 181-199 (through *Chem. Abstr.*, 1943, 37, 6518<sup>9</sup>). Types of hollow fibres, open, closed hollow, open septate, and closed septate, with apical, basal or intermediate growth, are discussed from the point of view of aluminium hydroxide fibres and silicate fibres. Such fibres are essentially membranes with liquid contents. C.

**Porous Solids: Permeability to Gases and Liquids.** L. Grunberg and A. H. Nissan. *J. Inst. Petroleum*, 1943, 29, 193-225 (through *Chem. Abstr.*, 1943, 37, 6517<sup>6</sup>). The authors have not established any correlation between the permeability of porous media to gases and to liquids. Permeability to gases depends mainly on the "Reynolds number," defined as the mean linear speed of the gas. Permeability to liquids depends not only on the viscosity, but also on the density and the surface tension. Temperature is a factor for the same liquid but a correction for this can be calculated. C.

**Organic Compound Solutions: Viscosity and Molecular Structure.** H. Staudinger. *Z. Elektrochemie*, 1943, 49, 7-16 (through *Chem. Abstr.*, 1943, 37, 6524<sup>8</sup>). The viscosity of solutions of compounds with small molecules is described. The relation between the viscosity number and molecular weight is developed and verified by experimental data on organic compounds in various solvents. The viscosity of colloidal solutions is considered and the relation between the viscosity number of the molecular weight or chain length of substances with large molecules (colloidal) is developed in agreement with experimental data. C.

**Plastics in Organic Solvents: Viscosity/Concentration Relations.** H. Eilers. *Kolloid Z.*, 1943, 102, 154-169 (through *Chem. Abstr.*, 1943, 37, 6523<sup>8</sup>). Since in solutions of organic substances of high molecular weight the volume of the disperse phase is greater than would appear from the volume of the dry material, the author's previously proposed equation for emulsions must be corrected for the increased bulk by the factor  $V$ . This is found to be a function of concentration. When the rheological concentration,  $V^{1/3}C_v$  (where  $C_v$  is the volume of dry particles), is greater than 0.65, deviations occur because the particles no longer fulfil the requirements of being spherical, non-deformable and equal in size. Data from the literature for solutions of phenol-formaldehyde resins in acetone, polystyrene in tetralin, poly- $\omega$ -hydroxydecanoic acid in *sym*-tetrachlorethane, polyethylene oxide in dioxane, cellulose acetate in *m*-cresol, nitrocellulose in butyl acetate, and rubber in chlorobenzene are studied in the light of equations developed. C.

**Polymer Solutions: Viscosity.** G. V. Schulz and Gertrud Sing. *J. prakt. Chem.*, 1942, 161, 161-180 (through *Chem. Abstr.*, 1943, 37, 6540<sup>4</sup>). The method given earlier for calculating the viscosity number is confirmed by measurements on polyisobutylene, polymethacrylate esters, polystyrene and poly-11-hydroxyhendecanoic acids. It is found that the viscosity constant is independent of the nature and the molecular weight of the solute for the above compounds, the nature of the solvent and the molecular branching. The concept of a limiting concentration and the influence of the solute are discussed. C.

**Electron Microscope; Electron Diffraction in —.** M. von Ardenne, E. Schiebold and F. Günther. *Z. Physik*, 1942, 119, 352-365 (through *Chem. Abstr.*, 1943, 37, 6542<sup>9</sup>). Electron-diffraction patterns of small regions in the field of vision of an electron microscope can be obtained by adding a magnetic lens of short focal length which causes a reduction of the diameter of the electron beam to values from 1 to 150  $\mu$ . By means of a simple mechanical manipulation, the position of the electron probe can be shifted to any point in the object plane. The co-ordinates of the point where the probe strikes the diffraction diagram yield the position of the probe in the object plane. The application of the method to fibre chemistry is discussed. C.

**Optical Linear-dynamo-dilatometer.** E. Wöhlisch. *Kolloid Z.*, 1942, 100, 151-153 (through *Chem. Abstr.*, 1943, 37, 6499<sup>8</sup>). The apparatus, equipped with an optical reading device, enables a complete thermodynamic analysis to be made of linear elastic changes in a highly elastic specimen during, for example, expansion and decompression. With this apparatus the thermal changes in the elastic tension at constant length can be determined, as well as the thermal changes in the length at constant tension at any degree of expansion. C.

**Isotropic Plastic Solids: Stress-Strain Relations.** W. Prager. *J. Applied Physics*, 1944, 15, 65-71. Combined torsion and tension of thin-walled tubes constitutes one of the few testing arrangements in which a fairly general state of

uniform stress can be realized without too great experimental difficulties. A manner of representing graphically the results of such tests is used in a discussion, in geometrical terms, of some stress-strain relations of the mathematical theory of plasticity. It is shown that the theories of Saint-Venant, Lévy, and Mises lead to physically unacceptable conclusions unless the material is supposed to be rigid as long as the stresses have not reached the yield limit. The predictions of the theories of Prandtl, Reuss, Hencky, and Nadai are compared with the results of experiments on mild steel; the possible effects of viscosity and strain hardening are discussed. C.

**Polystyrene: Effect of Ultrasonic Waves.** G. Schmid and E. Beuttenmüller. *Z. Elektrochemie*, 1943, 49, 325-334 (through *Chem. Abstr.*, 1943, 37, 6522<sup>9</sup>). Experiments have been made on the effect of high-frequency sound (284 kilocycles) on the decomposition of polystyrene in mixtures of solvents of different densities at 50°. The density of the solvent has no effect on the decomposition. This leads to the conclusion that the decomposition depends on the difference in the deformability between the polystyrene molecule and the solvent. C.

#### PATENTS

**Cellulose Acetal Derivatives: Preparation.** Carbide and Carbon Chemicals Corporation. U.S.P.2,329,741. Partially alkylated cellulose acetals are prepared by the interaction of a water-soluble partially alkylated cellulose with an aldehyde of the formula  $R \cdot CO \cdot CHO$ , where R is H or an alkyl radical. The products are insoluble in water, acetone and the lower alcohols. C.

**White Mineral Wax: Protection Against Light.** Socony-Vacuum Oil Co., Inc. U.S.P.2,331,469. A white, refined paraffin wax is protected against darkening on prolonged exposure to light by the admixture of a small amount of triamyl-, tributyl-, diamyl-, dibutyl-, or mono-butyl-amine. C.

### 10—ECONOMICS

**Rayon: Production in the United States, 1933-43.** *Rayon Textile Monthly*, 1944, 25, 5. The growth in the production of rayon in the United States is shown graphically. For 1943, the totals were 524 million lb. of continuous filament and 167 million lb. of rayon staple. The classification by process is given as viscose nearly 68 per cent., acetate nearly 27 per cent., the new group comprising Aralac, Nylon, Vinyon, etc., over 4 per cent., and cuprammonium over 1 per cent. C.

**Rayon: World Production, 1942.** *Rayon Textile Monthly*, 1944, 25, 8. A table records reliable data for 1939 of continuous filament and rayon staple production in all the known producing countries and the best available estimates for 1942. Attention is called to the extraordinary rise of 56 per cent. since 1939. Rayon staple production has increased by 87 per cent. and in the United States has trebled itself. C.

**Textile Wholesale Prices, February, 1944.** *Bd. Trade J.*, 1944, 150, 101. The wholesale price index numbers for February are Cotton 139.5, Wool 182.8, Other textiles 133.7 (1930=100). C.

**Textile Operatives' Earnings, July, 1943.** *Textile Weekly*, 1944, 33, 404. Average earnings in the first pay-week of July, 1943, and percentage increases over the last week in October, 1938, are tabulated for men, youths and boys, women, girls, and "all workers," in the main branches of the textile industry. C.

**Weaving Wage Lists: Improvement.** H. Brookes. *Textile Manufacturer*, 1944, 70, 56-59. Criticisms of the present "Uniform List" are enumerated and attempts to simplify the system are reviewed. The writer advocates a system that is based on the loom instead of on the cloth produced. Each loom would be credited with a "permitted maximum speed" and there would be every incentive to increase the loom efficiency. A "standard percentage efficiency" would be ascertained for the loom by tests involving reasonable expenditure of skill and energy by the operative and there would be a "standard wage" for maintaining this efficiency. Hypothetical cases are worked out. C.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY, AND EDUCATION

**Corrosive Acids: Handling.** U.S. National Safety Council. *Textile World*, 1943, 93, No. 12, 102. Methods for removing acids from carboys, and precautions to be observed in handling acids are enumerated in concise paragraphs. C.

**United States Textile Research Institute: Applied Research Programme.** G. E. Hopkins. *Textile Research*, 1943, 13, No. 14, 12-13. The applied research work will attempt to develop the application of fundamental principles to a point where competent mill technical staffs can "pick up the ball." The Director hopes to visit the technical staffs of all members to learn their problems and from these to select common denominators, of value to sections of the industry, and requiring more comprehensive study than may be afforded by individual laboratories. The contacts will include all laboratories working in the textile field. In addition the work of the engineering laboratories, the equipment manufacturers, the chemical industry and the electrical industry will be closely followed. The establishment of a large independent laboratory is not contemplated. The research committee, supplemented by consultants to be called upon according to particular problems, will subcontract the actual work to existing facilities, textile schools, engineering schools and sometimes members' laboratories. The functions of the applied research section are defined as recognition and definition of common problems, determination of the principles involved in their solution, selection and provision of proper facilities for their study, and the interpretation and distribution of the results. C.

**United States Textile Research Institute: Organization and Plans.** F. S. Blanchard. *Textile Research*, 1943, 13, No. 14, 4-7. A report is given of the organization, progress and future plans of the U.S. Textile Research Institute. A number of supplements and information reports on mildew-proofing of military fabrics, water-repellency, fire-proofing, bibliography of nylon, handling of high density cotton, etc., have been issued, and a committee on economic research has been set up. It has been decided (1) that the Institute should cover all branches of the textile industry, and all fibres; (2) that the laboratories should be near but not in New York; (3) that the Institute should have a five-point programme covering (a) fundamental research, (b) applied research and mill contacts, (c) a graduate school in affiliation with a leading university, (d) economic research, (e) information service, publications, abstracts, library, etc.; and (4) that a research fund of \$300,000 a year for five years, or \$1,500,000 plus a capital fund of \$500,000 should be solicited from all major branches of the industry. The Textile Research Institute is working in close cooperation with the Textile Foundation. C.

**Cotton Bacterium: Characteristics.** B. H. Caminita, R. Schneiter, R. W. Kolb and P. A. Neal. *Publ. Health Rep. Wash.*, 1943, 58, 1165-1183 (through *Bull. Hygiene*, 1944, 19, 41). An illness caused by inhaling cotton dust has been attributed to the endotoxin of the "cotton bacterium." The present paper describes the characters of 107 strains of this organism. It is a capsulated motile Gram-negative bacillus forming mucoid, often yellowish colonies. Failure to form indole, negative methyl red reaction, positive Voges-Proskauer and growth in sodium citrate identify it as an *Aerobacter* and gelatin liquefaction and incomplete fermentation of glycerol further identify it as *A. cloacae*. By the study of many other characters the 107 strains were separated into three types, with a fourth miscellaneous group: that designated Type I predominated, and it is this type which has been shown in various ways to possess the endotoxin to which mill fever is attributed. Serological studies showed the group to be antigenically heterogeneous. Information is also given about pathogenicity for animals, viability under natural conditions, and the effects of inoculating cotton plants. C.

**Formaldehyde Resin Dermatitis: Prevention.** K. E. Markuson, T. F. Mancuso and J. S. Soet. *Industrial Medicine*, 1943, 12, 383-386 (through *Bull. Hygiene*, 1944, 19, 39-40). Phenol- and urea-formaldehyde resins are primary skin irritants. On exposed parts a fine rash appears, associated with itching and erythema; scratching accentuates the condition, but most cases improve with

care. After recovery, individuals become hardened or immune to further contact, but this immunity may be lost and then severe dermatitis may follow. The onset usually occurs from three to six weeks after the initial exposure to the resin; the majority of cases are mild, and do not interfere with work. Under warm conditions, fumes rise from the resin and may cause conjunctivitis and redness of the face. Prevention is first an engineering problem to minimize the exposure in every way by introducing machinery to replace manipulation, by keeping processes enclosed, by controlling the escape of dust and fumes into work-places, and by keeping benches, floors and other surfaces clean. Protective clothing, kept scrupulously clean, must be worn; exposed parts may be protected with ointments and creams; frequent washing must be insisted upon. Workers must be taught how to work so as to avoid exposure. C.

**Light Metal Splinters: Injurious Effects.** *Industr. Bull.*, 1943, 22, 251-253 (through *Bull. Hygiene*, 1944, 19, 39). Splinters of light metal alloys of the Dural group, containing 93-95 per cent. aluminium, 3.5-4.5 per cent. copper, 0.6-0.8 per cent. magnesium, and smaller amounts of silica, manganese and iron, cause inflammatory reactions when they pierce the skin. The magnesium is responsible for the disturbances. Two or three days after a splinter has gained access to the skin a reaction develops which involves the surface and the deeper tissues. A local abscess may follow, with lymphangitis and lymphadenitis. A worker may also develop eczema and itching after three months' exposure to the dust. The splinters of light metal alloys have small barbed hooks, which attach themselves to the skin. An agar culture medium which contained light metal grew an astonishing number of such organisms as staphylococci, but when treated with heavy metals remained sterile. Magnesium in tissues results in decomposition of water, with the formation of vacuoles containing bubbles of hydrogen. The condition usually heals without any disability in under 14 days. Visible splinters should be removed; hydrogen peroxide bubbles help to float them to the surface. The dissemination of light metal dusts in workshops should be controlled; after work the skin should be carefully cleaned, and so should all tools used. Such care has appreciably reduced the number of cases. C.

**Time-study Board.** C. Hintz. *Machinist*, 1944, 87, 97. A board for time-study observations which holds the stop watch in line with the work and holds the analysis sheets so that they will neither slide nor curl is shown. It is cut from a  $\frac{1}{4}$ -in. sheet of laminated, duck-base phenolic plastic and guides for the analysis sheets, made of strips of stainless steel, are provided on the upper, lower and right-hand edges. The guides project  $\frac{1}{8}$  in. above the surface of the board, allowing a substantial stack of analysis sheets to be held at one time. A spring clip at the upper right-hand corner helps to hold the sheets in position. A projection near the right-hand top corner carries a watch holder which supports the stop watch at an angle of  $30^\circ$  to the board. A board designed for  $8\frac{1}{2} \times 11$  in. sheets can conveniently be held on the left forearm and grasped around the projection which holds the watch. This assures a steady rest while recording times and a convenient control of the stop watch.

**Halowax Acne: Occurrence and Prevention.** C. K. Good and N. Pensky. *Arch. Dermat. & Syph.*, 1943, 48, 251-257 (through *Bull. Hygiene*, 1944, 19, 125-126). A report is given of 52 cases of "Halowax acne" ("cable rash") following contact with Halowax, a mixture of chlorinated naphthalene and diphenyl, used for insulating electric cables. In making connections, the Halowax is removed from the copper strands, thus generating a fine grey dust; heat may be required to effect connections and fumes may then arise. The effects and symptoms are recorded. Most cases improved under treatment in cool weather, but in a few the eruption persisted for 18 months after freedom from exposure. Skin cleansing with soaps and ointments is indicated. X-Ray and ultra-violet therapy were of value in relieving symptoms and hastening recovery. Risks were lessened by the provision of blower and exhaust fans; frequent washing was called for; special soaps and skin creams were provided, as well as overalls, face masks, sleeves and trousers. Such clothes, however, by increasing sweating seemed to make matters worse. Experiments are in progress with new pentasols applied to the skin. No evidence has come to light that Halowax causes any systematic disturbance. C.

**Operatives: Psychology and Management.** May Smith. *Textile Weekly*, 1944, 33, 435-436. A condensed report of an address to mill managers on the symptoms of fatigue, vocational guidance and selection, motion and time study of operations, and the importance of the sympathetic and balanced character of the manager. C.

**Co-operative Research for Indian Industry: Organisation.** Sir S. S. Bhatnagar. *Indian Textile J.*, 1943, 54, 105-106. Developments in the production of chemicals in India are outlined, and the organization of co-operative research in England and the work of the Research Associations are discussed. The formation of similar organisations in India is recommended, and it is suggested that a centre of industrial research in connection with the chemical industry could be started in Calcutta University. The need for large Government grants and for donations from industry for industrial research is pointed out. C.

**Research Workers: Education and Place in Industry.** A. P. M. Fleming. *Engineer*, 1944, 177, 234-235. A report of an address to the Manchester Chamber of Commerce. Research workers are divided into two broad types: (1) those engaged in the pursuit of knowledge for its own sake—the workers in pure or fundamental science, and (2) those engaged in applying the new discoveries to useful purposes—the applied or industrial research workers. The functions and education of both types are discussed, and it is pointed out that, whereas it is not essential for the researcher in pure science to have industrial experience, such experience is necessary for the industrial research worker. In the chemical industry the best plan may be to continue for a few years a post-graduate course in an advanced field of chemistry, and then to enter a laboratory in the chemical industry. It may be preferable for an engineer to leave the university on graduation and spend the next year or two as an apprentice in an engineering firm possessing a research organisation. After acquiring a knowledge of works organisation and problems he would proceed to the research laboratory. Such a plan is practicable only in the large organisations with established research facilities and in the national interests large industrial concerns should be willing to train research workers for their entire industry. An alternative would be to use the facilities of the Research Associations on the lines of the plan developed by the British Cotton Industry Research Association. The industrial research worker should be trained to sell his abilities and to give service in such a tactful way that his help is welcomed and not resented. The large concern with its own research organisation is able to bring quickly to bear on its problems all new relevant scientific knowledge, but the small concern is at a disadvantage and manufacturing firms in this country are mostly small. The solution would be for each small company to have at least one technically-trained officer able to translate and make effective all the appropriate new knowledge provided, e.g. by the Research Association of the industry concerned. Comparisons with the United States and Soviet Russia indicate that in this country the quality of research is satisfactory, but the number of research workers is far too small. In the future, to an increasing extent, industrial problems will be undertaken by mass attack, and numbers will play an important part. Our disadvantage in this respect could be minimised by encouraging a scientific attitude of mind throughout industry and ensuring that technicians and artisans adopt that attitude of mind and mobility and skill which will enable them to turn new developments to account quickly. C.

**Russian Engineers: Education.** J. G. Tolpin. *Chem. & Eng. News*, 1943, 21, 2090-2099. The rapid development of industry in the Soviet Union since 1920 and methods used to stimulate production are discussed, and an account is given of the facilities for general and vocational education and of the aims, organisation and work of the engineering colleges. C.

**Swedish Textile Research Institute: Establishment.** *Textile Mercury & Argus*, 1944, 110, 289. It is reported that a new institute for scientific and technical research on textiles will soon be erected close to the Chalmers High School of Technology in Gothenburg, with which it will be associated. The machinery and instrument equipment are being supervised by Professors Hultin, Hoessjer and Svedberg and Chief Engineer Engblom. C.

## PATENT

**Loom for Occupational Therapy.** C. W. Harris. B.P.559,568 of 9/7/1942: 24/2/1944. A loom for occupational therapy is provided with a number of alternative means of performing one or more of the operations in weaving by different selected muscular movements or combinations of selected muscular movements of the patient. The loom is provided with alternative operating means such as drums, wheels, levers, pedals, roller paths or the like with readily attachable and detachable operative connections and (if and as necessary) jockey pulleys and guides or the like, which enable it to be set up at different times to suit a variety of patients. Details are given of a loom with various arrangements for operating the healds by wrist, arm, leg or foot movements. C.

# THE JOURNAL OF THE TEXTILE INSTITUTE

## ABSTRACTS

### LIST OF ABTRACTORS

The Abstracts in this section of the "Journal" are supplied by the following Organisations, and the source indicated by the initials hereunder shown.

British Cotton Industry Research Association	...	...	...	C.
British Launderers Research Association	...	...	...	La.
Bureau of Hygiene and Tropical Diseases	...	...	...	T.
Imperial Bureau of Animal Genetics	...	...	...	W.
Imperial Bureau of Plant Genetics	...	...	...	C. or L.
Linen Industry Research Association	...	...	...	L.
Water Pollution Research Board	...	...	...	W.
Wool Industries Research Association	...	...	...	W.

The original publications may be borrowed from or through the Institute library.

Any member wishing to borrow a journal should send to the Institute a copy of the reference which follows the author's name in each abstract, for example:—

"J. Soc. Dyers & Colourists, 1943, 56, 1921."

Members are requested to refund postage on the journals borrowed.

The letters B.P., U.S.P., D.R.P., in the references signify British, United States, and German patent specification respectively. These are not obtainable through the Textile Institute.

In some instances a second reference is given in parentheses as "(through *Chem. Abs.*, 1944, 34, 269)", which means that the abstract has been taken from another abstracting Journal and the original publication is not obtainable at the Textile Institute.

In this Section the abstractors give digests of reports published in technical and scientific periodicals of the whole world. The opinions and claims expressed in the abstracts are those of the original authors and it must be understood that the staff of the Textile Institute do not necessarily endorse them.

### 1—FIBRES AND THEIR PRODUCTION

#### (B)—ANIMAL

**Merino Skinfolts: Origin.** N. de la Harpe. *South African Merino Breeders' J.*, 1944, 6, No. 1, 19-20. Selection for greater quantity of wool necessitates selection for more intense activity of the physiological functions of the pelt. Expansion of surface area in the skin of the merino has been powerfully encouraged by selection for fleece density, with the consequent formation of skinfolts. This theory implies the closest relationship between skinfolts and the potentiality for high wool production. W.

**Stud Sheep.** G. E. McCabe. *South African Merino Breeders' J.*, 1944, 6, No. 1, 15, 17. Pepler's view that skinfolts in stud sheep should be discouraged (these *Abs.*, 1944, A45) is unsound. The ideal sheep has been gradually evolved, and if the stud animal were not developed the sheep would revert to its original hairy covering. W.

**Sheep: Development a Necessary Evil.** P. H. Brodie. *South African Merino Breeders' J.*, 1944, 6, No. 1, 11, 13. A small amount of skinfold (the animal in full wool appearing entirely plain-bodied) is necessary in stud sheep of the highest merit, so that flock sheep can have sufficient wool covering to make them an economic proposition. W.

**Sheep: Maintaining the Ideal Type.** T. B. Jordaan. *South African Merino Breeders' J.*, 1944, 6, No. 1, 8-9. Continuous use of only extremely plain-bodied sires would cause loss of staple formation and substance, which are the essential fleece characteristics of a stud merino. W.

**(C)—VEGETABLE**

**Cotton Crop: Influence of Climate.** C. B. Doyle. *U.S. Dept. Agric. Yearbook Separate* No. 1805, 1941, pages 348-363. A broad review of the influence of climate on the cotton crop, under the headings (1) Distribution of cotton-growing areas, (2) Weather conditions favourable for cotton, (3) Relation of climatic factors to yield, (4) Effects of exposure and harvesting methods, (5) Commercial types of cotton, (6) Principal regions of production (acreage and yields), (7) Cotton soils of the United States, and (8) Climate of the Cotton Belt. [No bibliography is provided but the review is valuable for its information about the American crop.] C.

**Bast and Leaf Fibres: Production in the Americas.** L. H. Dewey. *U.S. Dept. Agric. Misc. Publ.*, No. 518, 1943, 95 pages. A useful, illustrated account of the principal vegetable fibres, other than cotton and flax, produced in the Western Hemisphere. The main headings are (1) Classification and nomenclature; (2) Long or multiple-celled fibres, (A) hard or leaf fibres (henequen, sisal, letona, mezcal, zapupe, cantala, lechuguilla, Jaumave lechuguilla, furcraea, piteira, cabuya, fique, chuchao, cocuiza, pitre, common yucca, soapweed yucca, palmilla, banana yucca, mohave yucca, palma pita, palma barreta, Zaman-doque, Chaparral yucca, pita floja, phormium, abacá) (B) palm and palm-like fibres (Bahia piassava, Pará piassava, cabbage palmetto, scrub palmetto, pita de corajo, yaray, toquilla, (C) soft or bast fibres (hemp, cadillo, jute, ramie); (3) Short or one-celled fibres (kapok, pochote, Northern pochote, palo borracho, samohu); (4) Miscellaneous (broomroot, treebeard). The botanical names and descriptions are given and the production and marketing of the fibres are described. C.

**West Indian Cotton: History.** S. G. Stephens. *Tropical Agriculture*, 1944, 21, 23-29. The history of cotton growing in the West Indies during the 18th and 19th centuries is reviewed and extracts are given from historical records. Although cotton was found growing in the West Indies in some abundance by the early Spanish settlers in the 16th century, it does not appear to have attracted much attention for the next hundred years. The increased demand for cotton in the 18th century and the appearance of the sugar ant in the West Indies caused a rapid change from cane to cotton growing. The naked and tufted seeded varieties of cotton grown in the West Indies (shrub cottons) could be readily de-linted by roller gins whilst the green-seeded variety grown in the Southern States of America required hand de-linting and did not at first offer any serious challenge to the pre-eminence of West Indian cotton in European markets. After the invention of the Whitney saw-gin in 1793 American cotton production soared and West Indian production declined. In 1801 25,000 bales of cotton were shipped from the West Indies and by 1836 this figure had fallen to 20,000 bales. From then onwards cotton production rapidly diminished except for a short renewal during the American Civil War (1863-5) when cotton exports to Europe from the States were temporarily suspended. Only in the Grenadines did cotton growing persist into the 20th century. There appears to be no reason to suppose that perennial cottons found in the West Indies to-day differ from those cultivated in the 18th and 19th centuries. There is a strong possibility that *G. hirsutum* var. *marie galante* formed the major constituent of the crop. C.

**Bollworm: Control.** K. P. Ewing and E. E. Ivy. *J. Econ. Entomol.*, 1943, 36, 602-606 (through *Chem. Abstr.*, 1944, 38, 827<sup>4</sup>). Timely applications of heavy doses of calcium arsenate control *Heliothis armigera*. Light or improperly timed applications may result in heavier infestations of this insect on the treated than on undusted cotton plants. This increase is frequently associated with increase in aphid populations owing partly to the attraction of bollworm moths to the aphid honeydew. A more important factor is the reduced feeding of predacious insects on bollworm eggs when aphids are abundant. C.

**Boll Weevil and Bollworm: Control.** K. P. Ewing and C. R. Parcencia, Jr. *J. Econ. Entomol.*, 1943, 36, 607-610 (through *Chem. Abstr.*, 1944, 38, 827<sup>2</sup>). The comparative effectiveness of reduced dosages of calcium arsenate and the possibility of substituting cryolite for calcium arsenate for boll-weevil (*Anthonomus grandis*) control were investigated. Calcium arsenate, basic copper arsenate, lead hydroarsenate and cryolite were compared for effectiveness.

against the bollworm (*Heliothis armigera*). The boll-weevil population in the experimental plots was light, and few marked differences were evident between treatments. Calcium arsenate dosages of 8 lb. per acre failed to control the bollworm; 16 lb. per acre resulted in a significantly greater yield of cotton. Basic copper arsenate-sulphur mixture (1:2) at 16 lb. per acre equalled calcium arsenate applications of 12.5 lb. per acre in cotton yield. At dosages of 8 lb. per acre, basic copper arsenate, lead hydroarsenate or cryolite resulted in higher yields than the same dosage of calcium arsenate. C.

**American Cotton Crop: Post-war Position.** I. W. Duggan. *Textile Weekly*, 1944, 33, 626-630. A report of an address on the post-war prospects for American cotton. The following relevant facts are adduced: Exports of American cotton fell to about 1 million bales in 1940-41, but home consumption reached 11 million bales in 1941-42 and 1942-43. The world's supply of American cotton for 1943-44 is nearly 23 million bales. The "carry-over" at 1st August, 1943, was 11½ million bales, including a disproportionately large bulk of shorter staples and lower grades, but American mills demonstrated in 1942-43 their ability to use more of these growths. The American acreage for the 1943 season was 22 millions, and the crop estimate is 11.2 million bales; the record crop was 18 millions in 1937 and 1926. The acreage under cotton outside the United States in 1942-43 was 46 million and the crop 14 million bales; the largest relative reduction was in Egypt. Present production of continuous filament and spun rayon is equivalent to nearly 8 million bales of cotton. A plea is made for Government assistance to farmers so that the income from cotton may be increased. Nearly one-third of all the farm people in the United States live on cotton farms. C.

#### (D)—ARTIFICIAL

**Cotton Linters: Production and Application.** Emily L. Day. *U.S. Dept. Agric., Agric. Econ. Bibl.*, No. 88, 1940, 39 pages. Brief abstracts are given of 205 papers published between 1900 and 1940, classified under (1) General, (2) Methods of recovery, (3) Quality, (4) Commerce, (5) Uses, and (6) Legislation, regulation and adjudication. An index is provided. C.

**Unbleached Pulp: Action of Nitrogen Dioxide on —.** G. L. Clarke. *Paper Trade J.*, 1944, 118, TAPPI, 62-66. In an attempt to replace chlorine entirely or partly by other bleaching agents, experiments were made on the effect of nitrogen dioxide on unbleached pulp. When liquid nitrogen dioxide was introduced into an aqueous pulp suspension and the mixture was heated for 1 to 1.5 hours at about 90° C., the lignin constituent was so changed that it could be removed by hot caustic extraction. Since nitrogen dioxide in the presence of water is converted into a mixture of nitrous and nitric acids, the delignification cannot be carried to completion without considerable damage to the cellulosic constituent, which limits the use of nitrogen dioxide to the first stage of bleaching, comparable with the chlorination stage. After extraction with a small amount of hot caustic soda, the partly bleached pulp may be bleached to the desired colour with hypochlorite. If the brightness is limited to 70 to 75, a considerable amount of chlorine bleaching agents may be replaced by nitrogen dioxide. Pulp bleached in this manner had physical properties which were not very different from those of pulp bleached by the chlorine-hypochlorite method with cold caustic extraction between the stages. The α-cellulose content of the two pulps was about the same, but the viscosity was lower for the nitrogen dioxide-bleached pulp, probably as a result of the action of the nitrous and nitric acids formed. The indications were that the combined action of these two acids is responsible for the bleaching effect. It is suggested that the reaction comprises two phases, the nitration of the lignin residue and the oxidation of the nitrolignin, the latter phase resulting in the solubilization of the modified lignin. The nitrogen content of the treated pulp and the results of experiments with mixtures of sodium nitrite and nitric acid and with nitrogen dioxide and nitric acid seem to support this hypothesis. C.

**Sunflower Stalk Pulp: Production.** K. H. Rauch. *Angew. Chem.*, 1940, 53, 568-573 (through *Brit. Chem. Physiol. Abstr.*, 1944, B II, 37). A pulp which, after normal refining, was suitable for viscose was obtained by digesting sunflower stalks (fat + resin + wax 6.4, lignin 30, cellulose 37.6, ash 4.3 per cent.) with a liquor containing calcium oxide 0.98, free sulphur dioxide 1.86, and

combined sulphur dioxide 1.08 per cent. for 36 hours at 115-125° followed by bleaching for 10 min. at 30° with bleaching powder. The yield was 32.2 per cent. (α-cellulose 84.6 per cent.) and molecular size (viscosity method) 92,000. Analytical data are tabulated for pulps either isolated in the laboratory by hydrolysis (sulphuric acid alone or followed by caustic soda) and oxidation (nitric acid, chlorine, chlorine dioxide, or bromine) methods, or obtained on the semi-commercial scale by the caustic soda and kraft processes. A stable cellulose flour suitable for cattle fodder is obtainable as a by-product of the mechanical pre-treatment of the stalks. C.

**Man-made and Natural Fibres: Names and Sources.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 356-365. Lists are given of all the fibres that are available in commercial quantities, grouped into (1) man-made fibres and filaments, (2) animal fibres, (3) mineral fibres, (4) seed hairs, and (5) bast and leaf fibres. The names are in alphabetical order and parallel columns give synonyms, verbal descriptions (occasionally) and sources. Scientific names are in italics and the most common names in capital letters. C.

#### PATENTS

**Protein Filaments: Hardening.** A. McLean, S. R. Swift and Imperial Chemical Industries Ltd. B.P.559,818 of 2/9/1942:7/3/1944. A process for the production of protein filaments comprises extruding a solution of the protein, e.g. vegetable globulin or casein, into a coagulating medium, washing the filaments in an anti-swelling medium, maintaining the filaments in a solution containing an anti-swelling agent, e.g. sodium chloride, together with urea, thiourea, biuret, or like bifunctional amide, and thereafter treating the filaments under acid conditions and while they are still impregnated with the solution with a hardening aldehyde capable of reacting with the bifunctional amide in the presence of acid to produce an insoluble condensation product. For the production of staple fibre, the washed coagulated filaments may be cut and the staple fibre steeped in the solution containing the amide. C.

**Soybean Protein: Production.** Ford Motor Co. Ltd. B.P.559,848 of 11/5/1942:8/3/1944 (Conv. 10/5/1941). Protein suitable for use in the production of artificial fibres, paints, sizes, etc., is obtained by extracting protein from soybeans by means of alkali solutions, clarifying the protein solution, treating it with acid, decanting the liquor from the protein precipitate, dehydrating the precipitate by slowly freezing at a rate which encourages the formation of large ice crystals, thawing the frozen precipitate, and then decanting the water from the protein. C.

**Fibrous Pulp Liquid Treatment Apparatus.** Thames Board Mills Ltd., M. H. Morley and H. N. Baker. B.P.559,909 of 5/3/1942:10/3/1944 and 559,913 of 12/6/1942:10/3/1944. (1) A device for the treatment of fibrous pulp material with liquor consists of a tubular chamber of greater length than diameter having outlet perforations for excess liquor adjacent the discharge end only of the chamber, means to feed fibrous material and a digesting liquor to the inlet end of the chamber, a rotating screw conveyor in the chamber adapted to apply mechanical pressure to the fibrous pulp material while it is in the chamber, and steam inlets spaced along the walls of the chamber. (2) In apparatus of the type described in (1), a gear wheel mounted on an axis at right angles to the axis of the screw conveyor in the tubular chamber meshes with the flights of the conveyor to apply pressure to the material and is disposed to lie partly within a feed hopper for the tubular chamber and partly in a housing on one side of the tubular chamber. C.

**Rayon Staple Cutting Apparatus.** American Viscose Corporation. B.P.559,995 of 19/8/1942:15/3/1944 (Conv. 10/4/1942). In apparatus for cutting rayon staple, means are provided for continuously varying the rate of delivery of the continuous filament to the cutting device by varying the distance from the feeding device to the cutting device during operation, e.g. by moving the cutting device continuously toward and away from the feeding device. C.

**Staple Fibre Cutting Apparatus.** American Viscose Corporation. B.P.560,018 of 19/8/1942:15/3/1944 (Conv. 10/4/1942). In apparatus for cutting continuous filaments into staple fibres wherein the distance between cuts can be varied by varying the rate at which the filaments are delivered to the cutting

device, the feeding device comprises a variable-speed delivery roller or a rotatable member of non-circular cross-section which is driven either at constant or varying angular velocity. C.

**Wetting Agents: Application in Viscose.** Rayonier Inc. U.S.P.2,331,935/6. The conversion of refined pulp, containing not more than 0.15 per cent. of matter extractable by ether, into viscose is assisted by (1) adding to the mass before xanthation is complete an anionic surface-active agent that is soluble in the alkalis employed or (2) adding to the pulp a cation-active quaternary ammonium salt compatible with the alkali. The amount of wetting agent used is 0.01-0.15 or 0.20 per cent. of the weight of bone-dry pulp. C.

**Glass Fibres: Spinning.** G. von Pazsiczky (Hamburg; vested in the U.S. Alien Property Custodian). U.S.P.2,331,944/5/6. (1) Roughened glass fibres are obtained by blowing hydrofluoric or phosphoric acid vapours against the molten glass as it is being drawn into filaments. (2) Curly fibres are obtained by spinning a mixture of two glasses that differ in coefficient of expansion. Streams of the molten glasses flow together to orifices. (3) The claim is for a melting receptacle in which the molten glass flows in a thin film over a dam to the spinning compartment. C.

**Rayon Spinning Bucket.** American Viscose Corporation. U.S.P.2,332,314. A centrifugal spinning bucket is fitted with means for draining solutions or suspensions from its immediate surroundings and means for spraying it intermittently during operation. The effluent is automatically switched from one channel to another when spraying occurs. C.

**Cotton Drying Machine.** M. I. Teague (Rochester, Texas). U.S.P.2,332,413. The claim is for a machine in which a screen is arranged over the inner end of the air intake tunnel and a rotary brush works inside the screen to remove foreign matter. C.

**Vinylidene Chloride Polymer Yarn: Preparation.** Dow Chemical Co. U.S.P.2,332,485. A group of filaments of normally crystalline vinylidene chloride polymer is subjected in the supercooled condition to stretching and false twisting. A diagram of the apparatus is given. C.

**Gin Saw Cleaner.** James Delashaw and F. D. Gibson. U.S.P.2,332,783. The device consists of a set of discs on a shaft so spaced that the separate plates of the gin saw will fit between them when the saw is mounted for cleaning. The discs carry cleaning blades mounted at reverse angles to the rims of the discs so that the inner ends of blades on adjacent discs cross and override the saw teeth as the cleaner is rotated. C.

**Flexible Corrugated Spool.** Industrial Rayon Corporation. U.S.P.2,332,826. A radially compressible, flexible spool is made by forming into a cylinder a sheet that, in the illustration given, resembles deeply corrugated packing paper. C.

**Endless Belt Yarn Collecting and Winding Apparatus.** E. I. Du Pont de Nemours & Co. U.S.P.2,333,278/9. (1) Yarn (from a liquid treatment bath) is collected on a slowly moving endless belt from which it is removed (for winding into a bobbin) by means of a pair of tapered rollers so that the point at which the yarn is taken off the belt occurs at a pre-determined point from the forward part of the belt. (2) The arrangement is used for handling a crinkled yarn and the take-off mechanism is adjusted to apply tension so as to remove any desired amount of crinkle. C.

**Glycinin-Viscose Mixture Filaments: Spinning.** Tubize Chatillon Corporation. U.S.P.2,333,527. A homogeneous mixture of viscose and an alkaline solution of glycinin made with the help of a hydroxyalkyl sulphonylate is spun into an acid bath. C.

## 2—CONVERSION OF FIBRES INTO FINISHED YARNS

### (A)—PREPARATORY PROCESSES

**Electro-pneumatic Opening Machinery: Advantages.** C. Consterdine (Messrs. Platt Bros. & Co. Ltd.). *Textile Weekly*, 1944, 33, 512-8, 552-6, 594-600. A report of a lecture on the single-process system of cotton opening. Present difficulties in the production of good laps are ascribed to (1) high-density baling,

(2) the wide range of cotton grades due to the extension of cotton growing to new areas, (3) the demand for the reduction of dust in mills, and (4) the demand for better laps for the better functioning of the carding engine. Modern developments in machinery to meet these demands, especially the adoption of electric controls and pneumatic mixing and conveying systems, are reviewed in some detail and the following machines (by Platt Bros. & Co.) are mentioned. Hopper bale opener with electrically-controlled feeding lattice, Hopper feeder with creeper lattice and dust fan, Super-grid-area porcupine opener with feed lattice and Shirley cage and fan, Crighton opener cylinder fitted with by-pass valve, Hopper feeder with condenser and fan fitted with delivery regulator reserve box and wiper roller, Double opener consisting of one 24-inch cylinder and one pair of cages, one beater part with feed lattice, feed roller, cages and fan for down draught, and by-pass valve to miss the beater part if required, and Electro-pneumatic automatic distributor with one inlet and two outlet valves to distribute cotton to two scutchers. C.

**Cotton Card: Evening Action.** R. W. Vose and C. H. Plummer. *Textile Research*, 1944, 14, No. 1, 20-24. An experimental procedure was devised in which identifiable lap irregularities of known amounts were introduced and the resulting irregularity was traced in the card sliver. In order to produce the desired irregularities it was found more practical to alter the linear rate of feed of a uniform lap than to form a lap with definite irregularities in weight from point to point. A differential mechanism was used to control the irregularity in the feed of the lap to the card. Variations in the feed were created with wave lengths of 1, 2, 4, 8 and 16 in., each with amplitudes of 5 per cent., 10 per cent., 20 per cent. and 40 per cent. Records obtained on a sliver tester show the sinusoidal variation in sliver weight plus much smaller superimposed irregularities evidently originating in the card. To obtain an index of the card action in reducing the sinusoidal irregularity of the lap as fed, the irregularity of the sliver was compared with that introduced in the feed. The percentage standard deviation of the sliver was divided into the percentage standard deviation of the lap feed to obtain a decimal fraction indicating that part of the feed irregularity which passed through the card and appeared in the sliver. A chart is given showing the variation of this fraction with the wave length of the lap irregularity. Irregularities of wave length shorter than  $\frac{1}{2}$  in. in the lap were largely absorbed by the card and did not appear in the sliver. Irregularities of wave length longer than 8 in. were reproduced essentially completely, without any modifications by the card. In the range between these two wave-lengths the card exerted a partial evening action. C.

**Speed-frame Products: Effect of Doubling on Yarn Strength.** *Cotton (U.S.)*, 1944, 107, No. 12, 122-123. Further evidence is given on the question whether it is possible to reach the Draper standards for yarn strength with few doublings. The writer regards these standards as "rather ancient" and prefers the strength graphs issued by F. P. Sheldon & Son (1926), which give slightly higher values than the latest Draper figures for counts up to 10s and rather lower values for finer counts. Particulars of the speed-frame processes used are recorded and the average strength results obtained in 1942 and 1943 are tabulated. In 1942 the results were above the highest Draper figures in all of the 16 counts spun (4s to 20s) except in 17½s and 20s. In 1943 the results were not up to standard except in counts below 10s. The writer ascribes this rather to the poor quality of the crop than the processing. C.

**Faults in Woollens: Defects in Raw Wool and Yarn.** *Wool Rec.*, 1944, 65, 464, 466. If mechanical removal of burrs is not possible in carding, the piece good are either carbonised or burl dyed. The formation of neps in carding may be prevented by reversing the direction of revolution for one of the workers working over the intermediate swift. This reversal is also applied successfully for the prevention of slubs in the carded sliver by applying it to the last worker on the woollen carder. W.

#### (B)—SPINNING AND DOUBLING

**Hank Clock Production Factor Table.** C. McElroy and M. Gross. *Textile World*, 1943, 93, No. 4, 131. The table gives the factor by which to multiply the weight of cotton yarn required in order to obtain the corresponding number of hanks for a 240-spindle frame. Thus, assume that 1000 lb. of 36s has to be

spun; the factor for 36s is 0.15 and the hank clock reading for the 240-spindle frame should be  $0.15 \times 1000$ , or 150 hanks. C.

**Modern Cotton Spinning Mill: Installation.** J. Buckley (Messrs. Platt Bros. & Co. Ltd.). *Textile Manufacturer*, 1943, 69, 65-68, 115-118, 161-164, 207-210, 253-255, 299-301, 341-344, 389-392, 398, 431-435, 479-481, 529-531; 1944, 70, 19-22, 65-66, 87, 113-115, 159-161. This series of articles is an expanded version of a lecture (already noted) covering the equipment now in sight that would make the cotton mill of the future. The series is illustrated by 156 pictures of machines, mills and lay-outs, and the main chapter headings are: (I) Modern cotton spinning machines and methods; (II) Cotton opening and lap forming; (III) Do., dust extraction and waste recovery; (IV and V) Carding and combing; (VI) Ring spinning; (VII) Ring spinning and doubling; (VIII) Ring doubling; (IX) Large packages; (X) Packages and doubling rings; (XI and XII) Electric driving; (XIII) General mill conditions; (XIV) The complete modern cotton spinning mill; (XV) Future spinning mills. C.

**Worsted Spinning Nomograph.** M. C. Bishop. *Text. World*, 1944, 94, No. 1, 74-75. A nomograph showing delivery rate and bobbin filling time is illustrated, and its working described. W.

#### (D)—YARNS AND CORDS

**Glass Fibre Yarns: Uses.** H. D. Keiser. *Amer. Inst. Min. Met. Eng., Tech. Publ.*, 1598, 14 pp.; *Min. Tech.*, 1943, 7, No. 3 (through *Brit. Chem. Physiol. Abstr.*, 1944, B I, 23). Brief descriptions are given, with flow-sheet diagrams of the processes used in making various types of glass fibre. The products are used in military and naval electrical equipment for insulating purposes, as retainer mats in storage batteries, as light-weight thermal insulation for aircraft, as a material for sound insulation in factories, for making fireproof insulating board for covering steel plating of decks, bulkheads, or hull, for the tension core of field telephone cable, for parachute flare shields, and for insulating steam pipes and refrigerators. C.

#### PATENTS

**Apparatus for Reclaiming Fibre from Wool, Wool Waste, etc.** F. Kershaw and H. F. Raisbeck. B.P.558,675 of 14/1/1944. The material is fed into the upper end of a sloping, reticulated cylinder and removed from the lower end, grease and dirt being thrown through the reticulations and then through a hopper to a sack. The cylinder has a side to side shaking motion, the degree of movement being adjustable to suit the requirements of the material being treated. A beater assists the passage of the grease and dirt by striking the hopper when the cylinder is rocked. W.

**Reclaiming Fibres from Wool, Wool Waste, etc.** F. Kershaw and H. F. Raisbeck. B.P.559,307 of 14/2/1944. The fibres to be reclaimed are blended with a mixture of dust and sand, and passed through a willeying and then a shaking machine. The dust absorbs grease and dirt and the sand also acts as a scavenging agent by forcing the grease and dirt-laden dust through the apertures of the willeying machine. The reclaimed fibres are suitable for re-use in the textile industry, and the cleansing medium is used as manure, having the advantage of being free from long fibre. W.

**Spindle Bearing Oil Extracting Device.** Fine Cotton Spinners' & Doublers' Association Ltd. and E. A. Leigh. B.P.560,214 of 15/10/1942:24/3/1944. A device for the extraction of oil from the spindle bearings of spinning, doubling, winding and similar textile machines comprises a cylindrical oil receiver having a removable cover provided with three apertures, one carrying a junction having a bent pipe for insertion into a spindle bearing, the second carrying an inlet pipe connected to a source of compressed air for producing a vacuum in the receiver, and the third aperture provided with a drain plug or tap through which the contents of the receiver can be discharged. C.

**Textile Disintegrating Machine Teasing Drum.** F. A. and Sophie S. von Osten (South Orange, N.J.). U.S.P.2,331,943. The teasing drum of a disintegrating machine comprises a shaft and end discs connected by a number of rods that carry pivotally mounted, rigid pins projecting beyond the side discs. C.

**Novelty Yarn Spinning Frame.** Goodall Worsted Co. U.S.P.2,332,395. A frame for producing novelty yarns comprises front and back rollers for drafting

roving at a uniform speed and thickness, means to impart twist, and a pair of feed rollers in front of the above front drafting rollers to deliver a novelty-producing strand under uniform tension, but at a different speed from that of the roving, to the point where twist is being inserted into the roving. C

**Covered Chenille Strand.** Duro Persian Manufacturing Co. Inc. U.S.P. 2,332,833. A strand of chenille is run through a constricting device to lay the outwardly-extending fibres at an angle and then wrapped in a covering of fibrous material (yarn). C.

**Spindle Brake.** Whitin Machine Works. U.S.P. 2,333,047. The claim is for a brake that applies pressure at opposite points of the whorl of a spindle and consists of a pair of levers actuated by a toggle device. C.

**Self-lubricating Spinning Ring.** Herr Manufacturing Co. Inc. U.S.P. 2,333,069. The claim is for a ring combined with a well from which a wick leads lubricant to the bearing surfaces of the ring, the special feature being the provision of an enclosure for the wick in the well. C.

**Glass Fibre Yarns: Production.** Owens-Corning Fiberglas Corporation. U.S.P. 2,333,267. A mat of glass filaments collected on a spinning drum is cut by angularly displaced knives into strips parallel to the axis of the drum and these are then stretched into yarns and collected. C.

### 3—CONVERSION OF YARNS INTO FABRICS

#### (A)—PREPARATORY PROCESSES

**Nylon Yarn: Preparation and Weaving.** E. I. Du Pont de Nemours & Co. *Textile World*, 1944, 94, No. 1, 67-68. Practical advice is given on the processing of nylon. In winding, it is best to use tension devices of the whorl or rotating drum types. The double weaver's knot is preferred. Sized and oiled yarns give much wider tension variations than sized but not oiled yarns, but oiled yarns have other advantages. Suitable dyes for tinting are listed; they have to be added to the size. Yarn is sized single end by means of an aqueous solution of polyvinyl alcohol, about 4.5 per cent. being added. Such yarn is sized again in warp form; the taping of unsized nylon yarn has not been widely developed. Satisfactory tension in pirn winding is 20-35 grams for sized 60-den. yarn; low-twist unsized yarn, requires lower tensions. Conditioning should take place first in a very moist atmosphere and then in a normal one. Steaming of pirns results in width changes at each weft change. Weaving is best at 50-70 per cent. R.H. Because of trouble due to static electricity all metal parts with which nylon makes running contact should be earthed. C.

#### (B)—SIZING

**Cotton Warps: Sizing.** Textile Operating Executives of Georgia. *Cotton (U.S.)*, 1943, 107, No. 12, 91-95. A more complete record of answers to a questionnaire than one already abstracted. C.

**Electronic Instruments: Application in the Textile Industry.** S. T. Herr. *Instruments*, 1944, 17, 30-32. Applications of the photo-tube, e.g. in the spectrophotometer which may be used for control purposes in dyeing, a photo-electric weft straightener, photo-electric switches for various purposes, and electronic circuits applied to pyrometers are mentioned. The control of moisture content in warp sizing is discussed and the Moist-o-graph is briefly described. When applied to a tape frame, a small metal contact roller rides on the warp at the delivery end of the machine. The grid element of the measuring circuit is connected to this control roller and is responsive to the current which can be passed through the warp from an independent low-voltage source. This current is a measure of the electrical resistance, and therefore the moisture content, of the warp. By providing the instrument with a set of control contacts, and the tape frame with a suitable variable-speed drive, it is possible to set the control point at any desired moisture content and the unit will automatically maintain this value by adjusting the speed as required. In order to obtain the maximum benefit from the Moist-o-graph the size preparation, size box temperature and level, and cylinder temperature or pressure should all be under automatic control. C.

**Nylon Yarn: Dressing for Knitting.** *Silk and Rayon*, 1944, 18, 315-316. A brief review is given of patented methods for the dressing of nylon yarn for knitting by means of polyvinyl alcohol (prepared by the hydrolysis of polyvinyl acetate), sometimes partially etherified by acid condensation with formaldehyde, and blended with boric acid. C.

**Gum: Use in Size.** N. A. Mukoseev. *Tekstil. Prom.*, 1943, No. 1/2, 23-24 (through *Chem. Abstr.*, 1944, 38, 647<sup>6</sup>). A textile size, equal or superior to the usual starch size, was made by replacing half of a 90-kg. batch of rye flour (in 700 l. of water) by 24 kg. of gum arabic, heating nearly to boiling, adding 4 l. of a solution of castor oil 16.5, oleic acid 2.5, 20° Bé. caustic soda 7.5 in water 23.5 kg., and further adding 1 l. of oleic acid, boiling 20 min., and neutralising with acetic acid. C.

**Lime: Use in Size.** V. Korolev and V. M. Rybakova. *Tekstil. Prom.*, 1943, No. 4/5, 12 (through *Chem. Abstr.*, 1944, 38, 647<sup>6</sup>). A satisfactory textile size was prepared by mixing 100 kg. of rye flour with 700 l. of water at 20-25°, heating to 40°, adding gradually 8 kg. of lime in 100 l. of water, and, after 10-15 min., heating nearly to the boiling point. C.

#### (C)—WEAVING

**Picking Bowl: Fixing.** *Cotton (U.S.)*, 1943, 107, No. 12, 89, 96. The question is raised why different methods are used to fasten the picking bowl on some (American) looms. In reply two authorities say that on older looms it was usual to hold the bowl only by the cover that is used to prevent splashing of oil on the warp, that on more modern looms an extra cap screw is provided on the end of the picking bowl stud, and that on the latest models of Draper looms the cover is not used, but an Alemite fitting is carried by the cap screw to provide for the lubrication of the bowl. C.

**Shuttle Accelerometer and Speedometer.** I. H. Thomas and J. J. Vincent. *J. Sci. Instruments*, 1944, 21, 45-48. Two instruments are described which measure the speeds and accelerations of moving bodies, e.g. shuttles. The accelerometer is a null instrument in which the force exerted by a weight freely supported in the moving body is balanced by a calibrated compression spring. The final result is given in units of g. The principle of the speedometer, of which the theory is given, is based on the fact that a helical spring, moving longitudinally with a mass attached to its leading end, will extend if the other end is suddenly stopped. The extension of the spring is directly proportional to the speed of the moving body immediately before it is brought to rest and is not appreciably affected by variations in some of the characteristics of the moving body. The instrument gives the speed directly in feet per second. C.

**Loom Accessories: Storage.** J. H. Morriston. *Cotton (U.S.)*, 1943, 107, No. 12, 83-85. Practical hints are given on the storage and record-keeping of loom supplies with suggestions about the emergency supplies that the tackler should hold in order to save time. C.

**Smallwares: Weaving.** A. Thompson. *Textile Manufacturer*, 1944, 70, 128-131. A report of a lecture on smallware weaving in the Derby district, with illustrations of Heywood, Hattersley twin-web, Matterson 12-web mock-space batten, and Clutsom and Kemp shuttleless looms. C.

**Towel Fabric Warps: Preparation.** O. Pomfret. *Textile Manufacturer*, 1944, 70, 11-12, 29, 68-70. A practical account is given of the usual and special methods and machines for preparing ground and pile warps for towels. C.

**Weaving Shed: Management.** Textile Operating Executives of Georgia. *Cotton (U.S.)*, 1944, 108, No. 1, 79-82; *Textile World*, 1944, 94, No. 1, 82-83. Replies from 17 mills to a set of ten questions on practical problems in weaving are analysed. On the question of suitable humidity, a table summarises the R.H. per cent. aimed at, with particulars of the range of cloths manufactured in each mill; the lowest R.H. is 65 per cent., and the highest 87½ per cent. Three records of temperature are 80-84, 85 and 90° F. C.

**Weaving Shed: Management; Checking Defective Work.** J. Middleton. *Cotton (U.S.)*, 1944, 108, No. 1, 67-69. The writer discusses tactful methods of fixing the responsibility for bad work and stresses the importance of proper training for those operatives who do the cleaning. Too often, this is regarded as a suitable job for the newest operatives. C.

**(D)—KNITTING**

**Flat Seam Looping Machine.** J. W. Hughes. *Cotton (U.S.)*, 1944, 108, No. 1, 123-126. The history of the looping machine for joining the edges of a knitted fabric with a flat seam is traced and detailed instructions are given for operating the "Sotco" machine. C.

**(G)—FABRICS**

**Knitted Underwear: Production.** N. Wonnacott. *Cotton (U.S.)*, 1942, 106, No. 4, 157-8; No. 9, 243-6. A general discussion of modern production methods in an underwear factory with details of the arrangement of machines and work sheets for the manufacture of a standardized type of knitted shorts. C.

**American Army Wind-resistant Sateen: Construction and Processing.** *Textile World*, 1944, 94, No. 1, 66. Suitable mill organization is suggested to meet the requirements of the wind-resistant 9-oz. sateen adopted by the American Army for field jackets, with or without pile-fabric lining. C.

**Machine Gun Cartridge Belt: Production.** J. A. Hendley. *Textile World*, 94, No. 1, 69-71. The development of fabric belting for machine guns is briefly reviewed. Very large quantities are now being made in the United States from  $1\frac{1}{2}$ - $1\frac{1}{8}$  inch cotton. Two plain or duck fabrics are woven simultaneously with most of the warp threads passing through each other at intervals to form the cartridge pockets. On the loading edge of the belt the warps do not cross for a width of  $\frac{1}{8}$  to  $\frac{1}{2}$  inch, so that a continuous V-shaped entrance to the pockets is secured. On the bullet side the warps cross twice as often as in the main part so that secondary pockets are formed between the cartridges, the bullets are more rapidly aligned and the loaded belt lies perfectly straight. The main fabric is woven from 12/4s yarn, 8 turns per inch, dyed olive drab; there are 156 ends in belts for 0.50 cartridges and 106 for the 0.30 calibre. The belt is reinforced with 6-end lockstitch cord, wet twisted and treated under tension to remove stretch; 12 ends are used for the 0.50 calibre and 4 for the 0.30 belting. There are 38 or 36 picks per inch of the 12/4s yarn. Structure diagrams are given and also hints on weaving. The best results are obtained by using large section beams and weaving 4-8 pieces from each beam. The belts are finished water- and mildew-repellent. Inspection tests are described. There should be 29 pockets per yard for the 0.50 belt and 33 per 24 inches for the 0.30 belt. When cut to length, each 25th pocket is numbered for the gunner's guidance. C.

**Nylon Monofilament: Application.** T. G. Joslin. *Textile Manufacturer*, 1944, 70, 136-137. A series of illustrations are given of recent developments in nylon yarn, "wire" and plastics. The monofilament or "wire" is used in a window screen material for the weaving of which a special loom is shown. C.

**Terry Towelling: Construction.** O. Pomfret. *Textile Manufacturer*, 1944, 70, 104-106. Tables are given of length and weight per piece, width, numbers and counts of yarns used, weave, and ratio of pile length to ground for typical sorts of (1) terry robings and bib and feeder cloths, (2) nursery squares, (3) rollerings, (4) cotton hand towels, (5) condenser pile hand towels, (6) linen and cotton/linen hand towels, and (7) bath mats. C.

**Inflatable Life Rafts: Design and Construction.** J. G. Kreyer. *Mechanical Engineering*, 1944, 66, 121-129. An account is given of the design and construction of inflatable life rafts and of the accessories and other equipment used with them. The laminated processed fabric used for the main tubes of the larger rafts comprises a rubber coating of  $2\frac{1}{2}$  oz. per square yard on the outside of a basket-weave fabric, a similar rubber coating on the underside of the fabric, followed by a light-weight plain-weave fabric placed on a bias, a rubber coating of  $3\frac{1}{2}$  oz. per square yard with another ply of plain-weave fabric, placed on straight, and an inside coating of 1 oz. per square yard. This combination has a thickness of 0.033 in. and a nominal weight of 19.3 oz. per square yard. The basket-weave fabric is constructed of plied yarns of long-staple combed cotton. The plain-weave fabric is woven from single yarns of long-staple combed cotton and has 120 x 120 yarns per inch. An alternative to the basket-weave fabric is a 5-shaft fabric constructed of plied yarns of long-staple combed cotton. Square-woven ducks are used for the bottoms, carrying cases and pockets of the rafts. When applying the rubber coating compound, not less than eight spreads or coats per ounce per square yard of surface covered are used. "Mae West" life vests are made of single-ply coated fabric. C.

**What is Tweed?** E. S. Harrison. *Wool Rec.*, 1944, 65, 456, 458, 460. A survey of the development of tweeds, with particular reference to the implications of the word, and the question of dyeing. The cloth is described—not defined—as of medium weight, not very smooth in texture, tending towards Cheviot qualities and to broken colour effects, and definitely limited to woollen yarn. W.

**Wool Cloth Measures and Weights.** "A.A." *Wool Rec.*, 1944, 65, 327. The present anomalies and discrepancies could be removed by generally adopting the standard measure of 36 in. to the yd. without allowance, and by quoting weight per sq. yd. W.

#### PATENTS

**Fully-fashioned Hosiery: Knitting.** A. T. May. B.P.559,926 of 13/10/1942: 10/3/1944. In the manufacture of hosiery, particularly fully-fashioned stockings, a running-on course comprising a series of spaced eyelet holes is provided at appropriate points in the fabric, e.g. at the edge of the foot portion. The holes are preferably formed by transferring a predetermined number of needle or sinker loops on to the adjacent needles. C.

**Winding Machine.** J. Mackie & Sons, Ltd. and J. P. Mackie. B.P.559,927 of 17/10/1942: 10/3/1944. A machine for winding yarn into cross-wound packages or cheeses is provided with a helically grooved roller which may either run in contact with the yarn package or cheese, or may be additional to the roller which drives the yarn package by contact, the said roller having two oppositely directed grooves in its surface leading toward the ends from near the middle of the roller, the grooves being entirely independent. One is a right-handed and the other a left-handed helix. A moving guide member gives a comparatively small lateral displacement to the yarn so as to offset, first toward one side and then toward the other, the point from which the yarn extends to the grooved roller, the displacement being sufficient to carry the yarn over the centre line of the grooved roller and to cause it to enter the groove leading to the opposite end of the roller, thus ensuring that the yarn shall engage with the starting end, first of the right-hand helix and then of the left-hand helix, with a view to effecting the traverse toward the end of the roller and back again under the central displacement or biasing action. It is convenient to effect the biasing movement by means of a continuously rotating roller with a single continuous groove in it extending diagonally first in one direction and then back again so that the whole motion may be communicated by rotating elements without the necessity for any reciprocating parts. The rotating guide may, however, be replaced by any suitable form of laterally moving guide eye if preferred. C.

**Knitting Machine Yarn-control Device.** B. Toone (Nottingham) Ltd. and R. N. Toone. B.P.559,952 of 25/8/1942: 13/3/1944. A knitting machine having a yarn feeder displaceable between feeding and non-feeding positions, is provided with a yarn-control device located at the plain side of the needles to receive a withdrawn yarn on movement of the feeder to non-feeding position and to place the yarn for re-introduction to the needles on movement of the feeder to feeding position. The device may be applied to splicing and other mechanisms whereby a yarn is introduced into the fabric at intervals. C.

**Winding Machine Bobbin-identifying Apparatus.** Universal Winding Co. B.P.559,958 of 9/9/1942: 13/3/1944 (Conv. 11/9/1941). A winding machine is provided with a bobbin-identifying apparatus designed to apply an identification ticket automatically to a bobbin in such a position that the ticket is held in place by the yarn wound on the bobbin. The operating means are preferably arranged to actuate the ticket-supplying mechanism in timed relation to the winding operation of the bobbin. An electromagnet may be provided for operating the ticket-supplying mechanism and automatically controlled means may be arranged to control the energisation of the electromagnet. The identifying ticket may be applied to the bobbin from a continuous strip of tickets and the ticket-supplying mechanism is then preferably situated adjacent to the bobbin and is arranged to advance the ticket-strip to place a ticket between turns of the winding yarn to cause it to be gripped thereby with an end projecting from the bobbin. C.

**Snag-resistant Polyamide Knitted Fabrics: Production.** E. I. Du Pont de Nemours & Co. B.P.560,084 of 26/5/1942: 20/3/1944 (Conv. 14/2/1941). A method for the production of sheer knit goods, substantially free from snags

and pulled threads, from water-insensitive, continuous-filament, synthetic linear polyamide yarns, comprises applying an aqueous dispersion of a film-forming material which is tacky in the air-dried state, e.g. an alkyd resin, vinyl interpolymers, natural resin or a carbohydrate. With acidic resinous materials that are insoluble in water, dilute alkalis may be used to effect solution. In some cases it may be desirable to add a certain proportion of a water-miscible organic solvent to aid solubility and accelerate drying. C.

**Knitting Machine.** H. N. Smith and Elizabeth E. Smith (Daventry). B.P. 560,192 of 11/8/1942:23/3/1944. A knitting machine comprises looping means, a series of loop guard members and a series of new loop accepting members, the looping means being operable to form new loops through first one and then another of a course-wise series of previously formed loops on the guard members, each looping movement taking place relatively to a guard member which holds open the loop being penetrated, the accepting members being arranged to receive the new loops and the machine being so constructed and arranged to operate that the old loops are released from the looping means and transferred by relative movement between the co-operating guard and accepting members from the accepting members to the guard members in turn to be held open for new loops to be formed through them by the looping means. The guard members may be arranged to receive the new loops from the same side as such loops were accepted by the accepting members. This construction lends itself to a modification whereby two pieces of fabric may be knitted in the machine which may be joined at either or each end, in the first case to produce a single double width piece and in the second case a tubular fabric. The transfer of loops by the relative movement between the guard and accepting members may be aided by means co-operating therewith to keep the loops squarely related to the guard members during the transfer operation. The part of the guard member holding the loops is preferably a channel open at each end and the accepting member is received in the channel while the transfer occurs. C.

**Cop Winding Machine.** J. Mackie & Sons Ltd. and J. P. Mackie. B.P. 560,267 of 30/10/1942:28/3/1944. In mechanism for forming cops with tapered nose ends, a grooved roller is used for traversing the yarn over the nose of the cop, the roller is driven by the drag of the yarn in its groove, and is mounted so as to be retracted when required to facilitate starting of the winding, or piecing-up any broken ends of yarn, and to be returned to its correct position for winding purposes. The roller is constructed in two parts suitably fitted together and providing the guiding groove for the yarn between their opposing faces. C.

**Mock-fashioned Stocking: Production.** C. J. Toon and J. Toon & Sons Ltd. B.P. 560,312 of 20/1/1943:29/3/1944. A method of making a mock-fashioned stocking comprises the steps of knitting on a seamless knitting machine a length of tubular material comprising leg, ankle and foot parts, flattening the tube, cutting the foot part so as to provide a heel part and a strip of the material which is narrower than the tube and extends below the heel part, folding the strip back upon itself inwardly towards the heel part, attaching the then adjacent longitudinal edges of the strip to each other, and attaching the bottom edge of the strip to the then adjacent edges of the heel part so as to provide the instep, the toe and the sole of the stocking. In a preferred method, a seamless tube equal to the length of two stockings is knitted upon a tubular knitting machine and, during the knitting operation, the central part of the length of the tube of knitted material is automatically tightened in order to form the ankle and foot parts of the two stockings. After removal from the machine the knitted tube is flattened and cut so that it is separated into two lengths, each forming one stocking length and each comprising a narrow strip adapted to form the instep, toe and sole of the foot. Preferably the stocking is provided with an imitation seam at the back of the leg and with imitation fashion marks on opposite sides of the seam. It is also preferred to form a welt at the end of the stocking length of material during the knitting operation. C.

**Picker Stop.** Draper Corporation. U.S.P.2,332,366. The claim is for an adjustable element that bears against the top surface of the slay when engaged by the picker at a predetermined point of its travel. C.

**Reinforced Flexible Transparent Sheeting.** E. I. Du Pont de Nemours & Co. U.S.P.2,332,373. An open-mesh material made of nylon monofil is coated with a film of ethylene polymer, heated to the fusion point of the polymer, and rapidly cooled by quenching in a cooling liquid. C.

**Resilient Yarn Stockings: Knitting.** Paramount Textile Machinery Co. U.S.P.2,332,738. Stockings are knitted under low tension from a resilient yarn that resists the formation and retention of loops by feeding the yarn to the machine in intimate contact with a controlling yarn and afterwards removing this yarn. C.

**Rayon Winding Machine Thread Guides.** American Viscose Corporation. U.S.P.2,332,889. The claim is for a device for guiding the thread in the unwinding of a sequence of yarn packages so that when the trailing end of one package is united to the leading end of another the loop of joined thread may be kept out of the region of ballooning. C.

**Knitting Machine Fabric Draw-off Mechanism.** Textile Machine Works. U.S.P.2,333,074. The claim is for self-locking mechanism that engages by a downward movement with the fabric-engaging element without interference with the knitting frame. C.

**Moulded Plastic Bobbin.** Kilgore Manufacturing Co. U.S.P.2,333,340. The claim is for a bobbin moulded from a coloured plastic with stout ratchet teeth at either end. C.

**Textile Machine Batten: Reinforcing.** C. L. Huffman (Greenville, S.C.). U.S.P.2,333,377. A wood element for textile machinery that acts as a lever about a pivot is reinforced on either side of the hole in it by cutting diagonal bolt holes and filling them with dowel pins. C.

**Shuttle Weft Guard.** J. B. Daudelin and R. J. Messier. U.S.P.2,333,413. The claim is for a device located in the throat of the shuttle to stop an outwardly running balloon as the weft runs through the threading slot to the delivery eye. C.

**Circular Knitting Machine Adjustable Combination Stand.** Tompkins Bros. Co. U.S.P.2,333,572. A number of stands are mounted on a support that extends about the axis of the needle cylinder and are adjustable as a unit both radially and circumferentially. Slide means interconnecting the stands make some of them independently adjustable. C.

**Knitted Vulcanized Composite Fabric: Production.** Vanity Fair Mills, Inc. U.S.P.2,333,630. A base sheet containing latex is knitted through and then vulcanized. C.

#### 4—CHEMICAL AND FINISHING PROCESSES

(B)—BOILING, SCOURING, DEGUMMING AND WASHING

**Cottonin: Effect of Processing on Structure.** K. C. Menzel. *Klepszig's Textil-Z.*, 1943, 46, 4-9 (through *Chem. Zentr.*, 1943, i, 2257 and *Chem. Abstr.*, 1944, 38, 873<sup>1</sup>). The surface structure of the cottonin obtained from green tow by chemical disintegration is related closely to the degree of disintegration and greatly affects the spinning properties. It is affected appreciably by the presence of residues of the material that originally surrounded the fibre bundles and also by the condition of the middle lamella. The impurities of the tow from flax are attacked readily by alkali; those of tow from hemp, less easily. The cottonin can be improved greatly by thorough washing after the alkali treatment. The spinning properties of cottonin are damaged by bleaching. Acid pre-hydrolysis attacks the materials accompanying the cellulose, and occasionally causes the green tow to stick together. Acidification after the alkali boiling lightens the goods and improves the feel. Correct brightening makes the cottonin soft and flexible. Good cottonin can be produced even from raw material which is not very clean if the pre-cleaning, alkali disintegration, washing, brightening and mechanical after-treatment are well co-ordinated. C.

**Saponins as Detergents.** W. Kind. *Fette u. Seifen*, 1942, 49, 708-711 (through *Chem. Abs.*, 1943, 37, 6371). Saponins of various origin used in washing experiments on woollens and coloured goods failed to show any cleaning effects. W.

**Saponin as Textile Assistant.** H. J. Henk. *Zellwolle, Kunstseide, Seide*, 1942, 47, 131 (through *Chem. Abs.*, 1943, 37, 5870). The cleaning properties of saponin are due to negative electrostatic charges that peptize the dirt particles. The addition of 0.5-1.0 per cent. saponin to benzine prevents auto-ignition. W.

#### (G)—BLEACHING

**Continuous Peroxide Bleaching Range: Advantages.** W. W. Chase. *Textile World*, 1944, 94, No. 1, 76-78. A description is given of a new plant for continuous peroxide bleaching in open width, installed at the Riverside and Dan River Cotton Mills, Virginia. The units are (1) the cloth trolley, (2) a mangle for saturating the cloth with caustic soda, (3) a vertical heating tube, (4) a J-box, (5) a vertical washer, (6) an acid tank and mangle, (7) a vertical washer, (8) a travelling lattice, (9) a peroxide tank and mangles, (10) and (11) duplicates of (3) and (4), (12) and (13) two vertical washers, (14) drying cans, and (15) a winder. The treatment for an 8½-oz. herringbone twill and similar fabrics is outlined. The cloth travels at 50-60 yards per minute and the whole passage (including the piling in the J-boxes, which hold about 5400 yards) occupies about 2 hours 40 minutes. Costs for chemicals used are about 1.50 to 2 dollars, and the steam consumption is less than 750 lb. per 1000 lb. of cloth. C.

**Cellulose Fibres: Acid Bleaching.** P. P. Viktorov. *Tekstil. Prom.*, 1943, No. 1/2, 18-22; No. 3, 12-15 (through *Chem. Abstr.*, 1944, 38, 646<sup>9</sup>). Steep the material in water at 50-60°, after 36 hours wash with water at 50-60°, steep in a solution of sulphuric acid (5 g. per l.) at 60° for 12 hours, wash with water until neutral to Congo red, steep in a soap solution at 110-120° for 8 hours, drain and wash with circulating hot water for 30 min., wash twice with cold water, and treat with hypochlorite as usual. This process is particularly applicable to gauze. To prepare absorbent (hospital) cotton, heat for 4 hours in a sulphuric acid solution (0.5 g. per l.) with or without a wetting agent, wash with water, treat for one hour at ordinary temperature with an acid hypochlorite solution containing 1 g. per l. of active chlorine, rinse in water, bleach for one hour in an alkaline hypochlorite solution containing active chlorine 2 and silicate 2 g. per l., total alkalinity 0.5-0.8 g. per l., heating gradually from 30° to 60°, rinse with water, acidify with sulphuric acid (3-5 g. per l.), wash and dry at 50-60°. Some modifications of this procedure are discussed. C.

**Fur Bleaching.** W. E. Austin. *Text. Col.*, 1943, 65, 407-411, 429-430, 472, 519-521. A special technique is required on account of the diverse properties of skin and hair, and because an intense natural colour often has to be removed. Sulphites are used to bleach light-coloured furs by reduction, while pigmented furs are usually bleached by oxidation with peroxides. Solutions are applied by the brush or dip methods, ageing, drum bleaching (using an absorbent) or solvent bleaching. Deeply pigmented furs are best bleached catalytically with peroxides. The principles and mechanism of catalytic fur bleaching are discussed, and the methods of application described, the essential steps being "killing" (to remove grease and swell the fibres), application of the catalyst, bleaching and after-treatments. W.

#### (I)—DYEING

**Cotton Pile Fabrics: Dyeing.** *Textile Weekly*, 1944, 33, 407-9, 563-566. A general, practical account is given of the dyeing of cotton pile fabrics with direct, sulphur, vat, and basic dyes. C.

**Nylon Yarns and Fabrics: Dyeing.** E. B. Abbott. *J. Soc. Dyers & Col.*, 1944, 60, 55-59. The principal dyeing and fastness properties of dispersed dyes when applied to nylon are reviewed and compared with the properties of the dyes when applied to cellulose acetate rayon. The selection of dyes to be used in mixtures is discussed. The use of Solacet dyes for nylon is also discussed and differences in the behaviour of these dyes towards nylon and cellulose acetate rayon are described. The effects of certain physical properties of nylon on its behaviour in large scale dyeing are pointed out. C.

**Nylon Yarns and Fabrics: Dyeing and Printing.** *Silk and Rayon*, 1944, 18, 318. Brief particulars are given of new methods for dyeing nylon, including the use of formaldehyde sulphonylate in vat dyeing (B.P. 534,085; Imperial Chemical Industries Ltd.) and the reservation of nylon against direct dyes by means of sulphonic acid compounds (B.P. 552,015; I.C.I. Ltd.). C.

**Soap Solution: Dye Solubilization and Colloidal Micelle Content.** J. W. McBain and K. E. Johnson. *J. Amer. Chem. Soc.*, 1944, **66**, 9-13. The solubilization of insoluble dye by four potassium soaps containing 8-14 C atoms has been measured for equilibrium conditions over a range of concentrations. The solubilization increases so rapidly with the higher soaps as to cast doubt upon the suggestion that it is solution in the hydrocarbon fraction of the molecule and to favour the view that it involves incorporation between the layers of lamellar micelles. Potassium chloride not only greatly increases the solubilizing power of fully-formed micelles, but it produces in dilute solution micelles of still higher solubilizing power. C.

**Sodium Alkyl Sulphates: Adsorption by Fibres.** R. G. Aickin. *J. Soc. Dyers & Col.*, 1944, **60**, 60-65. The adsorption of sodium alkyl sulphates by wool has been studied under a variety of conditions. The single long-chain alkyl sulphate ion reacts with the basic groups present in wool and behaves as a colourless dye, in that the adsorbed ions cannot be removed by a simple washing process. Quite large amounts of the sodium alkyl sulphates are adsorbed, viz., up to 2.5 per cent. on the weight of the fibre, under neutral conditions. The extent of the adsorption increases with increasing H-ion concentration, and the concentration of the sodium alkyl sulphate solution is reduced almost to zero if there is less present initially than corresponds to the acid-combining capacity of the wool. The retarding and levelling action of these compounds in dyebaths can be explained in terms of this adsorption, since the dye sulphonic acids and the alkyl sulphates are competing for the same basic groups in the wool fibre, or active centres in other fibres. The extent and rate of adsorption are increased by the addition of electrolytes, the ion of sign opposite to that of the long-chain ion being responsible. As with interfacial tensions, the univalent ions fall into a lyotropic series. Measurements have also been made of the adsorption of sodium alkyl sulphates by cotton, silk, deaminated wool and nylon. The extent of the adsorption depends largely upon the number of basic groups present in the fibre. The curve for the adsorption by cotton is of the same shape as that for the adsorption by wool, showing that it is the single long-chain ion which is involved in both cases. With wool the adsorption increases over quite a long period, but with cotton it is complete in less than 30 minutes. The mechanism of adsorption thus appears to be different in the two cases. C.

**Luminescent Pigments: Characteristics.** G. F. A. Stutz. *Paper Trade J.*, 1944, **118**, TAPPI, 78-80. Fluorescent and phosphorescent pigments and their uses, and exciting light sources for these pigments are discussed. The chemical properties, daylight colour, fluorescent colour and brightness, afterglow, and other characteristics of fluorescent zinc and cadmium sulphides, the luminescent pigments that have found most use in printing inks, coated papers and filled papers, are briefly described. C.

**Peat, Brown Coal and Alder Bark Dyes: Application.** S. A. Bensman and G. N. Proshkin. *Legkaya Prom.*, 1943, No. 1/2, 12 (through *Chem. Abstr.*, 1944, **38**, 645<sup>6</sup>). Alkaline extracts of granulated peat gave dyeings on cotton that were not fast. Treatment of the dyed fabric for half an hour at 40-50° in a solution containing 1 per cent. of sodium dichromate and 2 per cent. of 30 per cent. acetic acid, and a 1 per cent. solution of copper sulphate removed part of the dye, but the remaining part was quite fast. Lignite extracted with boiling 40° Bé. caustic soda for 4-5 hours, filtered, and diluted with water, and applied to fabric which was then washed with acidified water and treated with dichromate solution, gave better results than did the peat extract. Caustic soda extract of alder bark was applied to cotton with a little ferrous sulphate, and to wool with ferrous sulphate and size. The cotton was dyed gray and the wool green-black. By using various metal salts there were obtained beige, brown, olive, black and other colours. Detailed experimental data are given. C.

**Aniline Black Dyeings: Production.** (1) B. V. Ponomarenko and A. A. Veliksel'skaya. (2) I. M. Khailov and E. A. Kondratenko. *Khlopchatobumazhnaya Prom.*, 1940, No. 11-12, 45-49 (through *Khim. Referat. Zhur.*, 1941, **4**, No. 7-8, 107-108 and *Chem. Abstr.*, 1944, **38**, 868<sup>5</sup>). (1) It has been proposed to add an excess of aniline to increase the mechanical strength of the dyed fabric on the assumption that free aniline neutralizes mineral acid.

Another view is that all free aniline evaporates during the dyeing process and, therefore, does not affect the strength of the fabric. Fabrics were dyed with aniline black dyes and the colour effect, the mechanical strength of the fabric and the concentrations of aniline in the air and in the drier, depending on the percentage of free aniline, were determined. Increasing the amount of free aniline in the bath caused increased volatilization of aniline, but did not improve the fabric. The limiting permissible content of free aniline is 5 per cent. (2) In dyeing cotton, in order to avoid as much as possible weakening of the fabric, and to produce a better colour, it is recommended to use aniline salt 10, copper sulphate 1, potassium dichromate 10 per cent. and the theoretical amount of hydrochloric acid required to displace dichromic acid from K dichromate; the temperature should be 20-25° and time of dyeing 1 hour. A preliminary treatment of the yarn with 0.5 per cent. solution of *p*-phenylenediamine is recommended. C.

**Dyed Silk: Treatment to Increase Fastness.** K. M. Markuze. *Shelk*, 1940, No. 12, 20-1 (through *Khim. Referat. Zhur.*, 1941, 4, No. 7-8, 108 and *Chem. Abstr.*, 1944, 38, 871<sup>3</sup>). The substantive and some neutral-dyeing acid dyes produce on silk fast colours in light and medium shades, but less fast colours in dark shades. Fastness can be improved by treatment with a condensation product of formaldehyde and dicyanodiamide. The method increases fastness to washing, does not decrease the light fastness, and leaves the shade almost unchanged. Treating rayon fabrics with the condensation product decreases their light fastness. C.

**Indanthrene Dyes: Application.** K. Stierwaldt. *Deut. Färber-Ztg.*, 1943, 79, 1-7 (through *Chem. Zentr.*, 1943, 1, 1719 and *Chem. Abstr.*, 1944, 38, 869<sup>8</sup>). A discussion of the classification of these dyes according to their absorption velocities, migration properties and levelling powers; newer dyeing methods, as the dyeing at 80-90°, dyeing in temperature stages with initial temperatures of 16-17° with the use of wetting agents, such as Igepon T or TS, Peregol OK, Humectol CX or Setamol WS; the pigment padding method with the use of an assistant, such as Eulyisin A; acid vat dyeing methods, etc. C.

**Substantive Dyeings: After-treatment with Chromium Salts.** G. Nitschke. *Textilberichte*, 1943, 24, 189-191 (through *Chem. Abstr.*, 1944, 38, 646<sup>4</sup>). Certain substantive dyeings can be improved in fastness by an after-treatment with dichromate and formic acid. This improvement is due to the power of formic acid to reduce Cr<sup>VI</sup> compounds partly to activated Cr<sup>III</sup> compounds. This after-treatment is applicable to substantive dyeings of staple fibre and cotton as well as to dyeings on semi-wool and wool-staple fibre mixtures; it can be employed in a two-bath or one-bath process. C.

**Sulphur Dyes: Application; Determination of Optimum Quantities of Sodium Sulphide.** N. N. Voznesenskiĭ and N. K. Sokolova. *Tekstil. Prom.*, 1943, No. 3, 8-11 (through *Chem. Abstr.*, 1944, 38, 646<sup>5</sup>). For sulphide determination the plumbate and the potentiometric methods are preferred to the iodometric. The plumbate method used with sodium ferrocyanide as external indicator is simple and reliable. The sodium sulphide requirements are different for various sulphur dyes and also depend on whether the dye is a powder or a paste and on the way it was stored. C.

**Dyes: Fading.** A. N. Terenin. *Trudy Chetvertogo Soveshchaniya Voprosam Anilinokrasochnoi Khim. i Tekhniki* (through *Khim. Referat. Zhur.*, 1941, 4, No. 9, 16 and *Chem. Abstr.*, 1944, 38, 871<sup>4</sup>). Precision physical methods are necessary for the complete explanation of the individual stages of the fading process. In a number of cases the application of the photochemical method explained the individual steps of the fading process. Fading is not a chain reaction; the retardation of fading by inhibitors is caused by the decomposition of the peroxide compound formed by the dye. C.

**The Dyestuff and Chemical Industry of Germany.** A. M. Ryde. *Dyer*, 1943, 89, 85-87, 125-127, 165-166, 173, 201-202, 239-241, 277-278, 309-310, 347-348, 387-388, 423-425, 457-458. A review of the growth and development of the German chemical industry, with particular reference to the activities of the I.G. Farbenindustrie A.-G. W.

**(J)—PRINTING**

**Chitin: Use in the Textile Industry.** P. P. Viktorov and I. M. Maïofis. *Khlopchatobumazhnaya Prom.*, 1940, No. 11-12, 52-53 (through *Khim. Referat. Zhur.*, 1941, 4, No. 7-8, 108 and *Chem. Abstr.*, 1944, 38, 874<sup>3</sup>). Chitin obtained from crab shells was deacetylated by treating 200 g. with 1000 c.c. of caustic soda (50° Bé.) at 120°, decanting the caustic soda, pressing out, washing and drying at 60°. The yield of chitosan was 90 per cent. Its highly viscous, colourless solution in acetic acid can be used as a thickener for printing and for finishing various fabrics. Chitosan solution is not washed from the fabric by alkali solution. C.

**Stencil-printing Frames: Cleaning.** A. Franken. *Deut. Textilwirt.*, 1942, 9, No. 17-18, 27 (through *Chem. Zentr.*, 1943, 1, 1001 and *Chem. Abstr.*, 1944, 38, 370<sup>9</sup>). Frames fitted with phosphor bronze gauze are cleaned with a solution of 1:1 caustic soda of 40° Bé. For silk gauze a solution of 3 c.c. of the same caustic soda per l. is used first and then a bath is used containing 4 g. of Biolase N extra powder, 1 l. of water (70°) and 0.5 g. of Nekal BX dry or else the bath contains 4 g. of Vival E conc., 1 l. of water (50°), 0.5 g. sodium chloride and 0.5 g. Nekal BX. The washing periods for these baths is 3 hours and the washing is repeated, if necessary. The chromium gelatin can be dissolved also with lactic acid. In all cases the frames must be rinsed thoroughly. C.

**(K)—FINISHING**

**Permanent Waving Preparations.** C. H. Allen. *Soap, Perfumery and Cosmetics*, 1943, 16, 392, 394, 397-8 (through *Chem. Abs.*, 1943, 37, 6088). Formulae are given illustrating the use of ammonia, ammonium carbonate, potassium carbonate, sodium carbonate, borax, monoethanolamine, triethanolamine, morpholine, ammonium sulphite, sodium sulphite, potassium sulphite, ammonium acetate, calcium oxide, calcium carbonate, ammonium sulphate, oxalic acid, barium chloride, copper carbonate, aluminium powder, potassium chlorate, copper sulphate, sodium chlorate, and a heat indicator of the mercuric iodide and cuprous iodide type. W.

**(L)—PROOFING**

**Electronic "Sewing" Machine: Application.** C. N. Hoyler. *Plastics Resins Ind.*, 1943, 1, 8 (through Mark & Proskauer's, *Resins, Rubber, Plastics Abstr.*, 1943, Sheet 680). An experimental electronic sewing machine is shown in which thermoplastic material to be bonded is advanced by a pair of rotating electrodes and exposed to a strong field for a few hundredths of a second. Very little power is required, e.g. two sheets of Vinylite, 0.004 in. thick, may be bonded in a seam  $\frac{1}{8}$  in. wide, at an inch per second with less than 10 watts. To accomplish the same result, two heated rollers would require a temperature of 180° C., and one roller operated over a platen would require a temperature of 370° C. In the electronic machine the heating is very uniform, and the heat conductivity of the electrodes keeps the outside of the material relatively cool so that the highest temperature is in the central part where bonding is supposed to take place. Devices for binding, hemming, or folding operations can be attached to the machine. For sealing packages, bar electrodes may be used. C.

**Copper Soaps: Rot-proofing Action.** P. B. Marsh, G. A. Greathouse, Katharina Bollenbacher and Mary L. Butler. *Ind. Eng. Chem.*, 1944, 36, 176-181. The results of soil burial tests show that copper naphthenate prevents rotting of cotton fabrics at lower concentrations than do copper oleate, "tallate" or hydrogenated resinate. Of these four soaps, copper naphthenate alone is able to prevent the growth of the copper-tolerant fungus *Aspergillus niger*. Naphthenic acid is effective in preventing the growth of *Aspergillus niger*, *Penicillium* sp., *Chaetomium globosum*, and *Metarrhizium* sp., and in preventing fabric deterioration in soil. Tall oil, oleic acid and hydrogenated resin show no protective value in any of these cases. Fabric treated with copper naphthenate, which has been drastically leached with dilute nitric acid until essentially free from copper, still has enough residual protection to prevent growth of *Aspergillus niger*; it is likewise protected against deterioration in soil. These facts indicate that the high preservative power of copper naphthenate is due in part to naphthenic acid. Fabrics treated with copper oleate, naphthenate and tallate lose copper readily at the points where the fabric is in contact with soil. Each of these compounds is insoluble in water, but may be solubilised by

acid hydrolysis or by reaction with materials which form soluble copper complexes. A neutralised sodium hydroxide extract of soils will dissolve copper from treated fabrics. Neutralised solutions of a variety of naturally occurring hydroxy and amino acids have a similar effect. Copper hydrogenated resinate is highly resistant to leaching. Its relatively poor protective power in contact with soils may be due in part to the low availability of ionic copper. C.

**Ozokerite: Use for Waterproofing.** N. P. Batsyn. *Tekstil. Prom.*, 1943, No. 4/5, 15 (through *Chem. Abstr.*, 1944, 38, 647<sup>b</sup>). Stearin, paraffin and aluminium oxide usually used for waterproofing were successfully replaced by ozokerite, waste fat and ferrous sulphate. An emulsion was prepared from ozokerite 150, waste fat 100, 32.5 per cent. caustic soda 16-20, 25 per cent. ammonium hydroxide 15-20 and water 180 g. Details of the application of the emulsion and the subsequent ferrous sulphate treatment are given. C.

#### PATENTS

**Wool: Chlorine Gas Treatment for Unshrinkability.** J. Brandwood. B.P. 559,263 of 11/2/1944. Wool, or similar fibre, in the form, e.g. of rovings or yarns, is wound into packages which are mounted on perforated holders of metal, metal alloy or other chlorine-resistant material, and subjected to the action of chlorine gas; the packages are cleared of residual gas by compressed air, and then washed. The winding is done so that a thin, even and permeable layer is presented to the gas. The gas (1-3 per cent. of the weight of the material, according to the degree of unshrinkability required) is preferably mixed with a large proportion of air at 5 lb./in. pressure. The apparatus used is similar to a yarn dyeing apparatus. Initial drying of the fibres is unnecessary; they may contain about 40 per cent. moisture. W.

**Wool Mixture Materials: Treatment to Reduce Shrinkage.** J. B. Speakman, T. Barr and Imperial Chemical Industries Ltd. B.P. 559,787 of 21/8/1942: 6/3/1944. A process for the treatment of loose fibre, yarn, or woven or knitted fabric consisting of or containing wool fibres to produce effects which include an increased stiffness, a reduced affinity for water vapour, and a reduced tendency to felt or, for woven or knitted fabrics, to shrink, comprises exposing the material at elevated temperature, but below 100° C., to the combined action of water vapour and the vapour of a volatile monomeric vinyl or vinylidene compound, e.g. an ester of acrylic or methacrylic acid, styrene or a vinyl ester, the temperature, time and other conditions of the treatment being such as to cause substantial polymerisation of the vinyl or vinylidene compound within the fibre. If the material is wetted out with water before exposure to the action of the mixed vapours, more even effects are obtained. If a polymerisation catalyst is required, the material may be impregnated with an aqueous solution of the catalyst. C.

**Fabrics: Coating.** Texproof Ltd. and R. H. Czczowitzka. B.P. 559,820 of 19/6/1942: 9/3/1944. A process of surface coating fabrics with a composition containing a polymerised organic compound, comprises first impregnating the fabric with a volatile liquid to form an emulsified layer of the composition at the surface of the material, which minimises permeation of the material by the coating composition, coating the material with a composition containing a polymerised organic compound, and drying the coated material. The impregnating liquid may contain small quantities of substances that modify its viscosity and wetting power, and also a precipitant for the coating composition. C.

**Transfer Marking Composition.** British Kaumagraph Transfers Ltd. B.P. 559,859 and 559,878 of 31/8/1942: 8/3/1944 (Conv. 17/9/1941). (1) A dye composition or transfer marking composition suitable for application to cotton, wool, silk or nylon fabrics comprises a dye, a non-resinous compound or compounds containing singly or collectively a phenolic group and a carboxylic group and capable of acting to fix the dye in the fibres of the fabric upon application of heat and in the absence of moisture or steam, together with a resin and/or a wax. The dye may be of the group Nigrosine base 2R, Methyl violet base, Rhodamine bases, Victoria blue base, Crystal violet. Salicylic acid is a satisfactory fixing or assisting agent. If desired a plasticiser, such as an alkyl phenol, may be added to the resinous material. (2) A heat transfer consists of a paper backing and a transfer marking composition printed thereon, the marking composition comprising a dye, an assisting agent or agents, namely, a com-

pound or compounds containing singly or collectively a phenolic group and a carboxylic group, and resin or wax or both resin and wax, the composition being capable of being released from the backing and caused to adhere to a textile fabric upon application of pressure at an elevated temperature below  $250^{\circ}\text{C}.$ , and the dye being capable of becoming fixed on the fibres of the fabric under the influence of the heat and pressure and of the assisting agent or agents, and while maintaining the composition in a dry state. C.

**Nylon Fabrics: Dyeing and Printing.** British Kaumagraph Transfers Ltd. B.P. 559,879 of 31/8/1942:8/3/1944 (Conv. 17/9/1941). A method of dyeing fabrics and articles containing nylon or other fibres comprises applying by dry heat and pressure, at a temperature less than about  $250^{\circ}\text{C}.$ , a composition containing a dye and a fixing agent. In order to facilitate printing it is preferable to include a resinous material and/or a wax as an ingredient of the composition. If the dye composition is to be used as a transfer composition, a wax is added. The fixing agent may be salicylic acid, or a phenol, together with a carboxylic acid. The dye may be of the group including Nigrosine base 2R, Methyl violet base, Rhodamine bases, Victoria blue base and Crystal violet. C.

**Anti-gas Clothing.** British Cellophane Ltd., G. S. Heaven and Zoe Heaven. B.P. 559,966 of 9/9/1942:14/3/1944. An article of clothing resistant to the passage of toxic materials including liquids and mists, such as mustard gas, consists essentially of two outer layers of leather or one outer layer of leather and one of fabric showing relatively low resistance to penetration by toxic material and between them a continuous interlayer of impervious sheet cellulose. The outer layers are united together around their edges to form a pocket, but are not united to the interlayer, which can be removed and replaced as desired. C.

**Rubber Bonded Cotton Fabrics: Production.** United States Rubber Co. B.P. 559,986 of 2/11/1942:14/3/1944 (Conv. 8/11/1941). A process for bonding rubber to plies of fabric containing cotton for the production of tyre casings, hose pipes, belting, etc., comprises applying to the fabric a coating of an aqueous rubber dispersion containing a quaternary ammonium compound in which one valency of the nitrogen is satisfied by an anion and the remaining valencies are satisfied by hydrocarbon radicals, drying the coating, applying a vulcanisable rubber composition, and vulcanising the composite structure. The anion of the quaternary ammonium compound may be any common ion, such as that of the hydroxide, halide, formate, acetate or sulphate radical. Specified quaternary ammonium compounds include benzylpyridinium chloride, trimethylbenzylammonium hydroxide and tetraethylammonium chloride. Tests have shown that the use of small amounts of these compounds in the manner described leads to a substantial increase in the flexible resistance of the rubber-fabric product. C.

**Cellulose Acetate Materials: Acid Dyeing.** D. M. Clark (Atlantic Rayon Corporation, Providence, Rhode Island, U.S.A.). B.P. 559,991 of 22/5/1941:15/3/1944. Secondary cellulose acetate, in the form of yarn, fabrics, films, etc., is dyed by treatment with an acid dye in an aqueous solution of an organic solvent of the cellulose acetate, e.g. formic or acetic acid, having a  $\text{pH}$  value below 1.4. The solution has a concentration between, on the one hand, the threshold concentration at which wetting and penetrating capacity toward the cellulose acetate become markedly greater than that of water, and, on the other hand, either the critical delustering concentration or the critical swelling concentration for the particular time and temperature conditions employed, and, if necessary, an inorganic acid is added to depress the  $\text{pH}$  value below 1.4. C.

**Printing Paste.** Hercules Powder Co. B.P. 560,049 of 5/12/1940:17/3/1944 (Conv. 10/2/1940). A textile printing paste has a total solids content not much above 20 per cent. by weight comprising a water-insoluble colour pigment dispersed in an emulsion comprising a continuous phase consisting of a solution of an insoluble cellulose ether in a volatile organic solvent and a discontinuous aqueous phase, the content of solids derived from the emulsion not exceeding about 10 per cent. by weight of the paste. If desired, a plasticizer for the cellulose ether or a suitable synthetic resin, or both, may be included in the solution of the cellulose ether. The printing paste may be applied to fabric by means of printing rollers or screens and the printed material dried at a temperature in

the range of 180° F. to 320° F. Development of the colour in the fabric and washing and soaping are not necessary. C.

**Thermoplastic Organic Materials: Heating by High Frequency Electric Fields.** E. I. Du Pont de Nemours & Co. B.P.560,101 of 14/9/1942:20/3/1944 (Conv. 13/9/1941). A process of inducing heat in thermoplastic organic materials comprises incorporating crystalline titanium dioxide (rutile or brookite) in the material and then placing it in an energized electrostatic field of radio frequency, e.g. between 100,000 cycles per sec. and 100 megacycles per sec. Suitable thermoplastic organic materials include polyvinylacetate resins, polyvinyl esters of organic and inorganic acids, polystyrene, polyacrylates, polymethacrylates, and cellulose derivatives. Applications of this method to the heating of adhesives in cementing operations are mentioned. C.

**Cellulose Ether Compositions.** British Industrial Plastics Ltd. B.P.560,115 of 25/8/1942:21/3/1944 (Conv. 26/8/1941). Water-soluble cellulose ethers are rendered relatively insoluble when heated in the presence of an acidic catalyst by incorporating in them a soluble methylated polymethylol melamine. The compositions may be used for the production of water-resistant films and coatings for the protection and decoration of paper, textiles, etc., and with suitable fillers for the preparation of moulding compositions. C.

**Patterned Cellulose Derivative Fabrics: Production.** British Celanese Ltd. B.P.560,116 of 1/9/1942:21/3/1944 (Conv. 3/9/1941). A process for the production of a patterned fabric comprises subjecting a fabric containing cellulose derivative filaments and carrying a resist in a pattern, to the action of a solution, of not more than 50 per cent. strength, of a non-volatile plasticizer for the organic derivative of cellulose in a volatile liquid which has some softening action on the organic derivative of cellulose, and then drying the fabric at an elevated temperature. The resist is preferably a water-soluble compound such as a soluble resin obtained from polyvinyl alcohol, a gum or protein material. The parts of the fabric exposed to the action of the plasticiser acquire a semi-stiff or organdie-like finish. The pattern effects are highly resistant to laundering. A similar process may be used for the production of pattern effects on films having a basis of cellulose acetate or other organic derivative of cellulose. C.

**Cellulosic Fibres: Treatment to Improve Resistance to Wet Processing.** Courtaulds Ltd., C. C. Wilcock and W. Armfield. B.P.560,121 of 17/9/1942:21/3/1944. To increase their resistance to wet processing cellulosic fibres are impregnated with an aqueous solution prepared from dicyandiamide or guanidine, resorcinol and formaldehyde and having a pH below 7, and then heated to convert the substances into a water-insoluble product. Cellulosic materials treated in this way do not suffer any substantial loss in affinity for wool dyes when they are subjected to crabbing, setting, scouring or milling operations. C.

**Methine Dyes: Production.** A. H. Cook and Imperial Chemical Industries Ltd. B.P.560,160 of 18/9/1942:22/3/1944. Di- and tri-methine dyes are made by condensing one molecular proportion of a quaternary salt of 3-methylquinoxalone, which may optionally be substituted in the 1-position by an alkyl, aryl or aralkyl group, with one molecular proportion of a cyclic aldehyde or, in one or more stages, with one molecular proportion of an arylformamidine or an ortho-formic ester which is capable of providing a methine group, and one molecular proportion of a heterocyclic nitrogen compound containing a reactive methyl or methylene group. The products dye acetate rayon and tannin-mordanted cotton in deep red, blue and violet fast shades. C.

**Halogenated Anthraquinone Dyes: Production.** Sandoz Ltd. B.P.560,164 of 8/12/1941:23/3/1944 (Conv. 13/12/1940). Halogenated dyes are prepared by treating derivatives of 1:4-diaminoanthraquinone of given general formula, which contain halogen in the 6- or 7- or 6- and 7-positions, with halogenating agents and, if desired, sulphonating the products so obtained. The treatment of 1:4-di-(2':4'-dimethyl)-phenylamino-6-chloranthraquinone, 1:4-di-(2':4':5'-trimethyl)-phenylamino-6-chloranthraquinone, 1-amino-2-bromo-4-(2':4'-dimethyl)-phenylamino-6(7)-chloranthraquinone and similar derivatives is described in examples. The dyes obtained dye wool in blue shades of good fastness properties which remain blue in artificial light. C.

**Aeroplane Fabrics: Tautening.** J. R. Myles, F. J. Siddle, D. Whittaker and Imperial Chemical Industries Ltd. B.P. 560,168 of 8/11/1940:23/3/1944. Fabrics, particularly fabrics stretched over light structures such as aeroplane wings, are tautened by doping them with a solution of the material obtained by chlorinating solid polythenes at a temperature generally below 60° C. to a chlorine content of 60-70 per cent. by weight, and preferably also one or more substances that inhibit the liberation of free hydrogen chloride from chlorinated polythenes under the conditions of exposure to light and/or heat, and if desired, other film-forming materials and/or plasticisers. Preferably, the first coat of dope is brushed on to the fabric and subsequent coats are sprayed, brushed or otherwise applied as convenient. C.

**Dyed Cellulose Fibres: Protective Treatment against Chlorination.** Society of Chemical Industry in Basle. B.P. 560,284 of 23/12/1941:29/3/1944 (Conv. 24/12/1940 and 25/11/1941). Cotton, linen or regenerated cellulose fibres which have been dyed with dyes sensitive to chlorine can be treated in baths containing chlorine without destroying the dyes, if water-insoluble condensation products of formaldehyde and urea compounds or similarly acting compounds are produced on the dyed material prior to chlorinating in such a manner that the condensation products are present in a coherent condition in or on the fibre. This treatment is especially valuable for the treatment of cellulose fibres which are to be mixed with wool and then subjected to chlorination to prevent the wool from felting and shrinking. Another suitable application of the process is in cases where undyed cellulose fibres have to be bleached by chlorination in association with dyed fibres. C.

**Cemented Pile Fabrics: Production.** R. S. Allen (Birmingham, Michigan, U.S.A.). B.P. 560,290 of 16/7/1942:29/3/1944. In a process for the production of cemented pile fabric by the method involving pleating a fibrous web about several separator strips, cementing a base fabric to each face of the pleated structure and then splitting the resulting structure in a plane parallel to the base fabrics, a pleated structure comprising a warp and several separator strips is passed through a confining passage formed by a pair of spaced parallel plates which are provided with longitudinally extending ribs. The mechanism for depositing the strips, one by one, in the mouth of the passage includes a pleating mechanism and a strip holding magazine co-operating with a strip transfer device adapted to receive a strip from the magazine. The transfer device first receives a strip from the magazine and then, moving from its receiving to its delivery position, it deposits a strip in the mouth of the passage, the pleating mechanism then folding the warp about the strip so delivered. The pleating mechanism may include a bar having a strip-engaging surface provided with openings which communicate with a suction passage and the strip transfer device may also be provided with suction passages controlled as by a number of cam-operated valves so that the strip is held on the delivery mechanism by suction until it is engaged by the pleating bar. The suction is then cut off from the transfer device and applied to the pleating bar, means being provided for operating the pleating mechanism so as to move its bar from engagement with the transfer device to the mouth of the passage when the suction is cut off from the pleating bar. Two pleating bars may be provided and two similar strip-holding magazines may be arranged on each side of the passage mouth. As the pleated structure leaves the confining passage, cement is applied to the bights of the warp by means of rollers which travel in the same direction as the pleated structure. In addition, the structure makes contact with friction rollers rotating in the opposite direction and at a greater speed than the cement applying rollers, so that the cement is rubbed or pressed into the loops before the structure passes through a drier, with the result that the initial cohesion between the cemented pleats is employed to maintain the number of tuft loops per unit of length. C.

**Cellulose Derivative Monoazo Dyes: Production.** British Celanese Ltd. B.P. 560,298 of 25/9/1942:29/3/1944 (Conv. 1/10/1941). Monoazo dyes are obtained by coupling 1-di(8-hydroxyethyl)-amino-3-acetanilide with the diazo compound of an aminophenylsulphone or an aminophenylmethylketone in which the benzene nucleus is free from further substituents. The products dye cellulose acetate and other organic derivatives of cellulose in orange shades which

are dischargeable to white and are of very good fastness to light, acid fading and dry bleeding. C.

**Wool Fabric: Mothproofing.** W. Colman and H. L. J. Haller (to the U.S. Secretary of Agriculture and his successors in office). U.S.P.2,318,201 of 4/5/1943 (through *Chem. Abs.*, 1943, 37, 6142). Isonitrosoacetanilide is used, preferably in acetone solution and with various other compounds. W.

**Dry Carrotting Fur on the Pelt.** J. D. Sartakoff (to No-Mercury Felt Corp.). U.S.P.2,321,775 of 15/6/1943 (through *Chem. Abs.*, 1943, 37, 6909). Pelts, e.g. English rack pelts, are tumbled with a relatively large bulk of pieces of substantially acid-proof attrition material, e.g. paraffin particles, substantially free from abrasive properties and dust and carrying a substantially imperceptible coating of adsorbed highly active carrotting solution, e.g. one containing nitric acid or sulphuric acid and hydrogen peroxide, and the attrition material is then separated from the pelts. W.

**Flexible Raincoat Coating Composition.** Columbus Coated Fabrics Corporation. U.S.P.2,331,977. A flexible film-forming composition for raincoats, etc., comprises nitrocellulose, butyl acetyl ricinoleate as plasticizer, a reaction product of castor oil, maleic anhydride and glycol as "flexibilizer," diatomaceous earth as a filler, a pigment, and a solvent. C.

**Nitrogenous Cellulose Derivative Materials: Production.** Röhm & Haas Co. U.S.P.2,332,047. Cellulosic fibre, yarn or fabric is treated with a solution of a condensation product of amino-1:3:5-triazine, formaldehyde and dimethylamine, and heated at 90-140° C. C.

**Starch Product: Preparation.** Corn Products Refining Co. U.S.P.2,332,320. A suspension of starch at 95-105° F. is passed through a chlorinating tower into which chlorine gas is supplied at the rate of 0.165-0.55 per cent. on the dry starch. The chlorinated starch liquor is mixed in a tank and allowed to settle for 180-50 minutes, when an antichlor is added and the starch is filtered and dried. A small amount of Na<sub>2</sub>H phosphate is added during the cooking of such starch (containing chloro-fatty acids) to minimize thinning. The product is described as a "thermophylic free starch." C.

**Dyeing Machine.** W. E. Rowlandson (Lowell, Mass.). U.S.P.2,332,346. The machine comprises a tank through which the fabric passes in festoon form and a mixing reservoir alongside the tank which has an upper part level with the top part of the tank, connected by a narrow channel to a lower part level with the bottom part of the tank. Perforated pipes within the tank feed the top and bottom parts with dye liquor from the top and bottom parts, respectively, of the reservoir. C.

**Shoe Stiffening Fabric: Finishing.** Celastic Corporation (Wilmington, Del.). U.S.P.2,332,501. A porous fabric is impregnated with 300-900 per cent. on its weight of a polyester-polyamide formed by the interaction of a C<sub>6</sub>-C<sub>10</sub> alkyl diamine, a C<sub>4</sub>-C<sub>8</sub> alkyl dibasic acid, and ethylene or propylene glycol, the ester-forming ingredients comprising 80-100 per cent. of the composition. C.

**Retarded-exhaustion Finishing Dispersion.** E. I. Du Pont de Nemours & Co. U.S.P.2,332,817. The exhaustion of a positively-charged aqueous dispersion of a finishing agent is retarded by the addition of 0.02-0.5 per cent. of a cationic surface-active agent, based on the weight of the textile material. C.

**Rubber-cored Yarn Laminated Fabric.** J. A. Grabec (Czechoslovakia; vested in U.S. Alien Property Custodian). U.S.P.2,332,848. Elastic sheet material is formed by embedding a fabric made from rubber-cored, textile-covered yarn in rubber sheeting under heat and pressure sufficient to unite the two supplies of rubber, and then vulcanizing the assembly. C.

**Polyvinyl Chloride Plasticizing Agent.** W. Gruber and H. Machemer (Germany; vested in U.S. Alien Property Custodian). U.S.P.2,332,849. An aliphatic ester of diacetoxystearic acid is claimed as plasticizing and thermally stabilizing agent for polyvinyl chloride. C.

**Nylon Fabric Articles: Finishing.** Paramount Textile Machinery Co. U.S.P.2,333,160. Articles manufactured from synthetic linear polyamides are pre-set by treatment in the unconstrained state with an aqueous medium at a predetermined temperature, then given a hot liquid treatment at the same or a

lower temperature, and finally re-set on a form by the action of an aqueous medium at a higher temperature. C.

**Cellulosic Fibres: Enhancing Dye Affinity.** General Aniline and Film Corporation. U.S.P.2,333,203. Cellulosic material is heated with pyridine or quinoline (if desired, in an indifferent diluent) and a compound of the formula  $R \cdot O \cdot CHY \cdot Hal$ , where R is a radical with up to 6 C atoms, or benzyl, and Y is H or methyl. C.

**Azo-dyed Cellulose Derivative Fabric: Discharge Printing.** Celanese Corporation of America. U.S.P.2,333,204. The material is printed with a discharging composition, aged, and washed at 10-35° C. in an alkali hydroxide or carbonate solution that is not sufficiently concentrated to injure the material. C.

**Singeing Machine Burner.** M. R. Kelly and J. T. Melton. U.S.P.2,333,381. The burner consists of a gas pipe with a slot along one side and a compartment, spaced from the pipe and encircling all but the slot region, through which a cooling liquid is conducted. C.

**Fabric Printing Drum.** C. P. Kent (Lyndhurst, N.J.). U.S.P.2,333,382. A perforated, rotatable drum houses a series of paint or lacquer containers that can be fed with pigment under pressure. Each container has a top opening, normally closed by a plug, through which the pigment enters and a bottom opening that is regulated by a segment-shaped plate and is kept clear by an oblique doctor blade. C.

**Arylaminoanthraquinone Dye for Cellulose Acetate.** E. I. Du Pont de Nemours & Co. U.S.P.2,333,384. Compounds of the formula  $RO \cdot C_6H_4 \cdot NH \cdot C_{14}H_9O_2 \cdot OH$ , in which R is  $-CH_2 \cdot CO_2H$ ,  $-CH_2 \cdot CH_2 \cdot OH$ ,  $-CH_2 \cdot CO_2Me$  or  $-CH_2 \cdot CO_2Et$ , and the NH and OH groups are attached to the anthraquinone system at positions 1 and 4, are claimed as violet dyes, fast to gas fumes, for cellulose acetate. C.

**Finishing Agent.** Montclair Research Corporation. U.S.P.2,333,623. The reaction product of formaldehyde, a nitrile ( $<9$  C), an acid chloride ( $>9$  C) and a tertiary amine is claimed. [The full specification says that agents of this type impart a soft, suede handle and that the impregnated cloth becomes water-repellent if baked at 140-170° C.]. C.

**Textile Material: Recovery from Rubber Goods.** R. E. Tefft (to Allied Chem. & Dye Corp.). Canadian P.407,228 of 8/9/1942 (through *Chem. Abs.*, 1942, 36, 6816). The material is digested at 120-160° with sulphur, a vulcanizing accelerator, and rubber solvent, e.g. anhydrous aromatic hydrocarbons, and the textile material then separated from the solution. W.

**Waterproofing Fabrics which Retain Air Permeability.** Textilwerk Horn A.-G. D.R.P.725,120 of 30/7/1942 (through *Chem. Abs.*, 1943, 37, 5874). The fabric is impregnated first with a paraffin solution, then with a dilute solution of a synthetic resin, e.g. polyvinyl acetate in benzene, and finally with a water-repelling solution, e.g. paraffin solution (for the second time). The fabric is then calendered at approx. 25°. W.

**Felt and Straw Hats: Stiffening.** I.G. Farbenind. A.-G. D.R.P.725,794 of 13/8/1942 (through *Chem. Abs.*, 1943, 37, 6142). Hats are treated with mixed- or hetero-polymers of at least one polymerizable olefinic compound having no free carboxyl groups and at least one olefinic monocarboxylic acid. Salts of such polymers can also be used. The hats are then treated with a salt solution which renders the polymer insoluble. W.

**Animal Fibres: Bleaching with Hydrogen Peroxide.** R. Sarg (to Elchemie G.m.b.H.). D.R.P.727,153 of 24/9/1942 (through *Chem. Abs.*, 1943, 37, 6470). Fibres, e.g. hair or bristles, are treated with reducing sulphur compounds and solutions of iron salts either simultaneously or consecutively. The bleaching is then finished as usual. W.

**Textiles: Milling.** J. Breuer (to L. Ph. Hemmer, G.m.b.H.). D.R.P.727,568 of 8/10/1942 (through *Chem. Abs.*, 1943, 37, 6908). The heat required for milling is supplied by an alternating current passed through the fabric. W.

## 5—ANALYSIS, TESTING, GRADING AND DEFECTS

### (A)—FIBRES

**Balls Sledge Cotton Sorter: Description and Application.** R. W. Vose. *A.S.T.M. Standards on Textile Materials*, 1943, 415-419. A brief description is given of the draw box and carriage of the Balls sledge sorter and their manipulation and use for plotting fibre length distributions. The accuracy of the instrument was checked by direct measurement of length on 25 fibres taken at each of a number of places on the plush spread. Except for one or two points the distribution of length of the 25 fibres was within the chosen limits and the averages for the 10, 15, 20, 25, 30 and 35 m.m. groups were, respectively, 9.7, 14.9, 19.4, 24.5, 29.2, and 33.0 m.m. This calibration is better than some reported by Balls; the improvement is ascribed to a superior quality of plush and to small mechanical modifications in the instrument. As typical of the use of the sorter, a set of frequency curves is given for a sample of cotton in the bale (12 bales) and in the scutcher lap, draw-frame sliver, card sliver, card strips and roving. C.

**Fibre Projection Apparatus: Application.** J. H. Graff and J. R. Feavel. *Paper Trade J.*, 1944, 118, *TAPPI*, 53-57. A projection arrangement for use in measurements of fibre dimensions consists of a projection microscope from which the microscope tube has been removed; in place of an objective, the microscope is equipped with an F 12.5 mm. f 2.8 projection lens. The microscope and illuminant are placed in a box-like table equipped with a reflecting mirror. The inside of the box is painted a dull black. On the top of the table-box and above the reflecting mirror is a ground glass (finely ground) on which a series of lines are drawn at 7.5 mm. intervals, representing an actual space between the lines of 0.1 mm. at 75 diameters magnification. Above the ground glass is a hood (the interior of which is painted dull black), which makes it possible to observe and read the dimensions of the projected fibres without disturbance from the light in the laboratory room. For measurements on pulp fibres, the fibres are stained with Bright stain and the pulp diluted so that 1 drop (using a dropper with 5-mm. inside opening) will contain about 25 fibres. One drop of the suspension is placed on each of eight slides. The slides are dried and the fibres are then treated with a drop of standard calcium chloride solution, straightened out with a dissecting needle and arranged side by side parallel to the length of the slide. The slide is then put on the stage of the projection microscope and fibre lengths are determined to the nearest 0.1 mm. and fibre widths to the nearest 0.01 mm. At a magnification of 75 diameters ray cells, fibre fragments and broken and whole fibres can be distinguished. A minimum of 200 measurements should be made. The arithmetic and weighted average fibre lengths, the average width, the length/width ratios, and the average area of the fibres, and also the percentage frequencies of the length and area can be calculated from the measurements. Results obtained for various pulps are tabulated and the advantages of comparing different pulps, as regards their relative percentages by weight of short, medium long, and long fibres, by plotting these values on a triangular chart are demonstrated. The influence of the size of the mouth opening of the dropper and the probable errors in average lengths and widths based on measurements of 100 to 1000 fibres are discussed. C.

**Cellulose-Water Adsorption Isotherm: Interpretation.** A. G. Assaf, R. H. Haas and C. B. Purves. *J. Amer. Chem. Soc.*, 1944, 66, 66-73. Three highly-swollen cellulose samples of cotton linters were studied by the thallous ethylate method. Extrapolation of the linear plots of methylation against molecular volume to volumes of 18 and 35 gave the respective percentages of cellulose theoretically accessible to water vapour and nitrogen gas. The moisture adsorption isotherms, at 20° or 25°, of the same swollen samples were determined. The moisture content at the second region of inflection in the sigmoid plots, occurring at R.H. about 50 per cent., was approximately that predicted from the results above by assuming the adsorption of one water molecule by each accessible alcoholic group. This region in the isotherm was considered to be approximately equivalent to a unimolecular water layer completely covering the accessible surface of the cellulose. The moisture content at the first region of inflection in the isotherm, occurring at R.H. about 10 per cent., was approximately one-third of the value at the second inflection. This fact, together with

other considerations cited, suggested that the avid adsorption of water up to the first inflection was mainly a function of the strong hydrogen-bonding capacity of the accessible, primary alcoholic groups. The intermediate portion of the isotherm represented the water less strongly hydrogen-bonded to the secondary alcoholic groups, but its shape was influenced at the higher humidities by the effects of swelling and by capillary condensation. Some physical-chemical implications of these ideas are discussed, particularly the inference that the moisture sorption characteristics of cellulose and starch at 80° or more must be those of the primary alcoholic groups exclusively. Up to 98 per cent. of the surface of moist, swollen cellulose was obliterated by direct drying, but up to 75 per cent. was preserved during solvent-exchange with ethanol. The adsorption of 6 per cent. to 9 per cent. of water increased the colloidal surface of highly swollen cellulose by at least 20 per cent., but the increase for unswollen samples was perhaps thirtyfold. These data throw fresh light upon the significance of the mercerisation or reactivity ratio of cellulose, which is usually given as about 1.5. The surfaces of two of the swollen cellulose samples were estimated by the standard method involving the determination of the nitrogen adsorption isotherm at  $-195.8^{\circ}$  but the correlation of this method with the thallous ethylate technique requires further study. C.

**Cupri-ethylenediamine Cellulose Solutions: Viscosity; Rapid Determination.**

R. M. Levy, P. Muffat and W. D. Harrison. *Paper Trade J.*, 1944, 118, TAPPI, 45-47. Details are given of a rapid method for the determination of the viscosity of cellulose in cupri-ethylenediamine solutions which is suitable for control purposes in pulp and paper mills. Moist pulp samples can be used without previous drying. The pulp is first subjected to a wet disintegration and then measured into a dissolving tube and mixed with an equal volume of double-strength cupri-ethylenediamine solution (1.0M. in copper). The pulp is stirred for 5 min. and the viscosity determined with a capillary viscometer. An aliquot part of the pulp suspension is also filtered on a Buchner funnel, dried on a steam cylinder, and finally weighed in a conventional type of heated pulp balance. The viscosity is then corrected to a standard weight from a set of simple tables. The entire test, including all operations in duplicate, can be carried out by unskilled workers in approximately 20 min., and results obtained which are reproducible within 1 per cent. or better. C.

**Fibres: Specification and Testing.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 457 pages. The following standard has been revised in 1943: D276, Tentative methods for identification of fibres in textiles (pp. 18-36). C.

**Rayon Staple: Commercial Weight Testing.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 257-259. "Tentative Method of Test for Commercial Weight of Rayon Staple," D540, lays down the conditions for sampling from the bale, preparing test specimens (about 300 gm.), "boiling off," and determining the moisture regain. C.

**Casein Bristles: Production and Properties.** T. L. McMeekin. *A.S.T.M. Bull.*, 1943, No. 125, 19-21. A general account is given of the production, properties and uses of casein bristles. Data showing the water absorption of untreated and formaldehyde-hardened fibres, lysine content, and flexibility of fibres prepared from various proteins are presented. Hardening agents for casein fibres are briefly discussed. C.

**Clam Muscle Fibrils: Electron Microscope Observations.** M. A. Jakus, C. E. Hall and F. O. Schmitt. *J. Amer. Chem. Soc.*, 1944, 66, 313-314. Electron micrographs show the fibrils obtained from the adductor muscles of marine and fresh-water clams to be very long and evenly contoured, with widths usually between 200 and 1000 Å. In fibrils treated with osmic acid the density along the axis is not uniform but shows a periodic variation producing a cross-striated appearance. From measurements of 100 fibrils a distribution curve of "spacings" of this fibre axis repeat pattern was constructed. All the values lay between 290 and 470 Å. The most frequently occurring spacings were between 330 and 390 Å., the average value of all spacings being 360 Å. X-Ray diffraction data indicate that the fibre axis period in the intact dried muscle is 720 Å. It is suggested that the larger X-ray period reflects density differences

not yet resolved with the electron microscope but which may become apparent when special methods are applied. C.

**Shirley Analyser: Application.** G. W. Pfeifferberger. *Textile Research*, 1944, 14, 50-54. The Shirley Analyser is briefly described. It is pointed out that there is a good correlation between Shirley Analyser waste percentages and combined scutcher and card waste so that rapid determinations can be made of the waste loss that may be expected in the mill. The relation between waste and grade is discussed and it is shown that an examination of waste may serve to explain some apparent discrepancies. "Grade" entails three factors—colour, leaf, and preparation. If two samples of cleaned lint are difficult to distinguish from each other, the difference in grade designation can be attributed to factors other than colour. If the cleaned samples differ in appearance, fibre deterioration as reflected by colour is indicated. Another useful application of the Shirley Analyser is for the analysis of mill waste products. A table is given showing percentages of clean lint recovered from samples of raw stock, finisher laps, finisher motes, card motes, flat strips, and cylinder and doffer strips. Average values are 97, 98, 45, 56, 89 and 96 per cent., respectively, indicating that a large part of the material now considered as waste is composed of good, usable fibre. This statement is substantiated by the results of fibrograph length tests on the reclaimed fibre. Fibrograph or array measurements used in conjunction with the Shirley Analyser would be useful for determining proper settings on scutchers, cards, combers, etc. The possibility of using the principle of the Shirley Analyser in the commercial cleaning of cotton either at the gin or in mill opening processes is discussed. C.

**Polyamide Fibres: Fine Structure.** K. Hess and H. Kiessig. *Naturwissenschaften*, 1943, 31, 171 (through *Chem. Abstr.*, 1944, 38, 181<sup>9</sup>). The condensation product of hexamethylenediamine and adipic acid or that of  $\epsilon$ -aminocaproic acid gives new reflexes in the meridian of the X-ray pattern (diatropic interferences) of period 74 Å., for poly- $\omega$ -hydroxydecanoic acid 79 Å., and for poly- $\omega$ -hydroxyundecanoic acid 65.5 Å. The reflexes are weaker for the latter two. The periods have no relation to the usual fibre period. Heating of the fibre increases the period length irreversibly. The exact origin is not given. C.

**Textile Fibres: Elastic Properties.** H. J. Henk. *Spinner u. Weber*, 1942, 60, No. 19, 14-15 (through *Chem. Zentr.*, 1943, i, 799 and *Chem. Abstr.*, 1944, 38, 872<sup>3</sup>). The elasticity of textile fibres is compared with that of rubber and is related to structure. Silk and cotton exhibit only slight true elasticity because of the stretched condition of their principal valence chains. Wool is highly elastic, owing to the possibilities of transformation of the  $\alpha$ - and  $\beta$ -keratin during the stretching. The behaviour of the polypeptide chains during stretching, reversible and irreversible stretching, the significance of the amino groups in irreversible stretching, and the effect of pH on the extent of the stretching are discussed. C.

**Wool Scale Cells: Electron-microscope Pictures.** H. Zahn. *Textilberichte*, 1943, 24, 137-160 (through *Chem. Abstr.*, 1944, 38, 646<sup>9</sup>). In the degradation of isolated scale cells with pancreatin, fibrils are set free which agree in their structure with those found in the spindle-shaped cells. The structures are very long, are arranged parallel and are 100-500 m $\mu$  wide. C.

**Wool: Testing Resistance to Bacteria.** B. Schulze and H. Sommer. *Textilber.*, 1943, 24, 105-108 (through *Chem. Abs.*, 1943, 37, 6465). Differently treated wool fabrics were subjected to the action of bacteria and of Burgess's trypsin solution, respectively. The wool damage was determined microscopically and titrimetrically. The microscopic method is more accurate and more sensitive. The attack by bacteria takes place more slowly than that by trypsin solution. Neither method can be substituted completely for the other. The use of *B. subtilis* alone or with wool-damaging bacteria made no difference in the results. Samples treated with Eulan N and chrome were fairly resistant to bacteria, but nearly all were attacked by trypsin solution. W.

(B)—YARNS

**Cordage: Testing.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 121-128. "Tentative Methods of Testing and Tolerances for Spun, Twisted, or Braided Products made from

Flax, Hemp, Ramie or Mixtures thereof," D739, lays down definitions, tolerances, and methods of sampling and determination of weight per unit length, breaking load, twist, diameter, alkali solubility, sizing and finishing material, regain, matter soluble in ethylene dichloride, and analytical values of the constituent waxes. C.

**Rope: Testing.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 117-120. "Tentative Methods of Testing and Tolerances for Rope (Leaf and Bast Fibres)," D738, lays down conditions for sampling and conditioning, and determination of weight per foot, circumference, length per turn, breaking load (dry and wet), extractable matter (solvent), and fungicides. C.

**Vinyon Yarn: Properties.** Carbide and Carbon Chemicals Corporation. *Silk and Rayon*, 1944, 18, 261. Vinyon yarn is spun from an acetone solution of a co-polymer of vinyl chloride (90) and vinyl acetate (10). The average molecular weight, according to the Staudinger viscosity rule, is 20,000. The freshly spun yarn is weak, but it is stretched by several hundred per cent. while hot and "set" under tension at 90-100° C. The filaments then have breaking loads of more than 4 gm. per den. They retain their dimensions at temperatures up to 65° C., but shrink at higher temperatures and become tacky at 135-140° C. Very fine filaments are spun, e.g. 10 fil. 8 den. yarns. The specific gravity is 1.34-1.36. Vinyon does not absorb moisture and is water-repellent, though it can be wetted if a wetting agent is used. It is resistant to acids, alkalis, salt solutions, cuprammonium, and organic solvents other than ketones, esters, amines and halogenated hydrocarbons. It is a non-conductor of electricity, is non-inflammable, and immune to mildew and bacteria. It has been used for filter cloths, for anode bags in electrolytic operations and for clothing in chemical work. C.

**Yarns: Designation of Construction and Twist.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 337-339. Examples are given of extensions of the S and Z system of designating yarn twist to include, in order, the direction of twist, the amount of twist and the type of fibre, the shilling stroke being used to indicate a folding operation. Thus, 100-60 Z 60 Viscose & 100-40 S 3 Acetate/2 S 12 designates a ply yarn made by twisting together one end of 100-den. 60-fil. viscose yarn having 60 t.p.i. of Z twist and one end of 100-den. 40-fil. acetate yarn having 3 t.p.i. of S twist, the ply yarn having 12 t.p.i. of S twist. C.

**Yarns: Specification and Testing.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 457 pages. The following standard has been revised in 1943: D508, Standard methods of testing and tolerances for yarns spun from mixed fibres. (pp. 47-51.) C.

**Yarn Calculation Tables.** Ernest Whitworth. *Textile World*, 1944, 94, No. 1, 64-65. The following "ready reckoners" are provided: (1) Table of yards per pound of various yarns in counts 1 to 9. (2) Conversion factors for seven count systems. (3) Table of equivalent counts of yarn in the same seven systems. C.

**Grex Universal Count System: Application.** A. G. Scroggie. *Textile Research*, 1944, 14, 36-39. Problems that would be met with in the adoption of the Grex count system are briefly discussed and suggestions are made for the conversion of testing instruments. Applications of the system to single and plied yarns are considered, its effects on yarn twist and fabric cost and conversion calculations and in the control of yarn manufacture and strength tests are indicated, and its advantages are pointed out. Extracts are given of letters from members of the American textile industry endorsing the system. C.

**Rayon Yarns: Use for Insulation of Fine Wires.** A. Brookes. *Engineering*, 1944, 157, 263-264, 281-283. Properties required in insulating materials for fine wires, particularly those for use in electrical equipment which may be exposed to tropical conditions, are discussed. Possible substitutes for silk are reviewed. Where space factor is of secondary importance, silk may in many cases be replaced by fine cotton, acetylated cotton (Cotopa), varnish-impregnated lapped paper or pulped paper. Glass fibre yarn is suitable for heavier gauges. Cellulose acetate rayon has been used in large quantities on large-gauge wires, switch-board cables, cords, etc., and proved superior even to silk for such coverings. A

light fusion of the surface of the covering after lapping by suitable heat treatment provides a covering of high abrasion resistance. "Fortisan" (regenerated cellulose) has great resistance to abrasion and excellent covering power. Durafil is also useful. Nylon is produced in filaments fine enough for wire covering, but is more expensive than the other types mentioned. Notes are given on the methods of production and properties of these various artificial filaments, yarn count systems are explained, and the results of tests of the different types of wire coverings are discussed. Average values of electric strength for silk coverings vary between 350 and 720 volts per mil, the most frequent value being of the order of 670 volts per mil. Fused cellulose acetate, single lapped, gives 730 volts per mil, as a median value, with 620 and 800 volts per mil as normal extremes. Nylon gives an average figure of 550 volts per mil. Figures for cuprammonium rayon and Fortisan coverings vary considerably with the humidity. Average breakdown temperatures of coverings are: cotton, 376° C.; Fortisan, 375° C.; cuprammonium and viscose rayons 365° C.; silk, 355° C.; nylon, 254° C.; and cellulose acetate, 220° C. In comparative abrasion tests, the highest resistance figures were obtained with a double-lapped cellulose acetate fused. Rayons do not permit minimum wire elongations of 20-30 per cent. as obtained with silk, but 15-17 per cent. is commonly attained with cellulose acetate. In general it can be said that where a textile covering is essential and the electrical properties and space factor demand a high standard, cellulose acetate, fused after lapping, and nylon are the most suitable substitutes for silk. Where electrical properties and moisture resistance are not so important, or if varnish impregnation is used, Fortisan may be used on good elongation wire and if, in addition, space factor is not important, the range may be expanded to include cuprammonium or viscose rayon strong yarns. C.

#### (C)—FABRICS

**Circular Knit Underwear Fabrics: Defects.** *Textile World*, 1944, 94, No. 1, 86. Illustrations are given of (1) loose stitch, (2) cut hole, (3) pulled stitch, and (4) needle mark defects in underwear fabrics, and causes and remedies are suggested. C.

**Fabrics: Air Permeability Test.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 61-62. "Tentative Method of Test for Air Permeability of Textile Fabrics," D737, lays down the conditions under which conditioned air is drawn through a known area of fabric, after establishing a known pressure gradient across the fabric (usually half an inch of water), and the volume of air is measured in some suitable way. The "air permeability" is expressed in cubic feet of air per minute per square foot of fabric at the stated pressure gradient. Tests are made at  $70 \pm 2^\circ$  F. and  $65 \pm 2$  per cent. R.H. C.

**Glass Fibre Fabrics: Testing.** Committee D13, American Society for Testing Materials. *A.S.T.M. Standards on Textile Materials*, 1943, 226-233. Particulars are given of the following new "Standard Methods of Testing and Tolerances" for Woven Glass Fabrics (D579), Woven Glass Tubular Sleeveing and Braids (D581) and Woven Glass Tapes (D580). C.

**Quality Control Charts: Applications in Cloth Production.** O. P. Beckwith. *Textile World*, 1944, 94, No. 1, 79-81, 134-140. An explanation of "quality control" by means of charts marked with upper and lower permissible limits of a test value. The importance of the correct selection of these limits is emphasized by some charts for the finished weight of a fabric. The advantages of "quality control" are enumerated. C.

**Wire Mesh Screens: Hydraulic Properties.** J. F. Halladay. *Paper Trade J.*, 1944, 118, TAPPI, 48-52. In a study of the flow of water through woven wire mesh screens of the type used in the paper industry use was made of a device comprising a Lucite tube 3.75 in. in diameter and about 40 in. long with a thin metal plate at one end having a circular aperture over which the cloth to be tested was fixed. Measurements were made of the time ( $t$ ) for a head of water in the tube to fall from an initial value  $H$  (in feet) to a value  $h$ . Tests were made with starting heads of 30 and 20 in., orifice diameters of 0.6875 and 0.91 in., and wire mesh screens of 40, 80, and 100 meshes per in. at water temperatures ranging from 44° to 122° F. It was found that the ordinary hydraulic laws governing discharge through orifices could be applied and  $t$  was given by

the relation  $t = 2A(\sqrt{H} - \sqrt{h})/ak\sqrt{2g}$ , where  $A$  = area of horizontal cross-section of vessel in sq. in.,  $a$  = area of discharge orifice in sq. in.,  $g$  = acceleration due to gravity, and  $k$  = discharge coefficient of orifice. A direct and practically linear relation was observed between the hydraulic discharge coefficient and the calculated open area of the wire cloth. Increase of about 80° F. in water temperature caused increases of not more than 10 per cent. in discharge coefficients.

C.

**Quality Control Charts: Textile Applications.** A. G. Ashcroft. *Text. World*, 1943, 93, No. 12, 69-71. Statistical control does not by itself make quality or uniformity, but assists in judging the significance of variations in the quality record. The technique is based on statistical theory, details of the sources of which are given, but the actual operation involves only simple mathematics. Charts, as used by Alexander Smith & Sons Carpet Co., U.S.A., are illustrated for controlling the weight, strength and yarns per in. of Army blanket and duck, and for recording the porosity or leakage values of duck.

W.

**Friction Meter for Determining the Coefficient of Kinetic Friction of Fabrics.** E. C. Dreby. *J. Res. Natl. Bur. Standards*, 1943, 31, 237-246. A friction meter, designed at the instigation of the American Society for Testing Materials and the National Bureau of Standards, with the object of developing methods for the evaluation of textile finishes, is described. One piece of cloth is drawn over a second piece, whilst the two are pressed together by a standard load. One end of this second piece is fixed to a clamp on a torsion element and the frictional force measured by the deflection of this element, recorded by a dial gauge. The factors which affect this dial reading, e.g. relative speed of the two patterns, load applied to the contact surfaces, repeated testing of the same two pieces, etc., are enumerated and their various effects described. These investigations lead to the formulation of a standard testing technique. Various applications to the evaluation of smoothness are given. An investigation on the coefficient of friction of 18 samples which had been graded for smoothness by a number of experts, showed (by the application of the Kendall method of rank correlation) that factors other than the coefficient of friction enter into an expert's judgment of handle. The combined use of 3 measurable characteristics of cloth, friction, flexibility and compressibility is given as an example of how it may be possible to evaluate handle by physical tests. Examples are given of the use of the friction meter for determining the effect of finishing treatments, e.g. finishing agents, calendaring, and laundering on the frictional properties of fabrics, as well as the properties of fabrics composed of different fibres and yarn and cloth construction.

W.

#### (D)—OTHER MATERIALS

**Gas Permeability Measuring Apparatus.** A. C. Shuman. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 58-60. Apparatus for measuring the gas permeability of film materials of low permeability is described and details of its construction are shown in a diagram. The method involves measuring with a manometer changes in pressure inside a small evacuated space due to gas passing through the test specimen. Results are recorded as c.c. of gas at standard conditions of temperature and pressure transmitted per 100 sq. in. of surface per 24 hours. The calculations are explained and results obtained with samples of laminated glassine and polyvinyl alcohol coatings are discussed. The apparatus can be used for measuring the gas permeability of film materials having permeabilities as low as 0.001 c.c. per 100 sq. in. per 24 hours.

C.

**China Clay: Electron Microscopy.** W. Eitel. *Ber. deut. keram. Ges.*, 1943, 24, 27-53 (through *Chem. Abstr.*, 1944, 38, 461<sup>9</sup>). Photographs were made by utilizing the differences of penetrability of particles by electrons. Kaolin is characterised by individual crystals having hexagonal outlines. Montmorillonite has a strong tendency to form finely flaked, leafy aggregates, which appear as a cloud in the electron microscope. The absorption of electrons is increased by exchanging the lighter cations of the montmorillonite for heavier ones. Halloysite has crystals shaped like a shoe last. Layer-forming tablets are shown by mica and its decomposition products, as well as talc and soapstone. The electron diffraction diagrams of the above clay minerals correspond with the X-ray diagrams. A tabular summary of the electron-microscopic interference fringes and spots furnishes the basis for the quantitative analysis of clays. A

potential of 70 kv. was used as a standard in preparing the summary. The electron-microscope picture of soapstone heated to 700° resembles that of unignited talc. Soapstone crystals heated to 800° become turbid and flake off. The interference diagram shows that at this temperature the talc crystals have completely disappeared and have been replaced by protoenstatite. Formation of the free oxides was not observed with talc. Recrystallisation of the protoenstatite begins at 900°. Soapstone heated to 900-1200° contains protoenstatite and cristobalite. Above 1200° protoenstatite passes irreversibly into stable clinoenstatite. The behaviour of talc on heating is similar to that of soapstone. Kaolin heated to 500° shows no change in electron-microscope picture or diffraction diagram. At 550-600° dehydration sets in and diffuse scattering halos appear in the diffraction diagram. Up to 800° these halos remain unchanged in position and sharpness, but increase in intensity with increasing temperature. These lines do not belong to mica, muscovite, or biotite. At 900° all of the kaolin lines have disappeared and the first lines of the mullite diagram are seen. Above 1100° these lines predominate. Finally typical lines of cristobalite appear. C.

## 7—LAUNDERING AND DRY-CLEANING

### (A)—CLEANING

**Detergents: Efficiency.** J. C. Harris. *A.S.T.M. Bull.*, 1943, No. 125, 27-33. A report is given of studies of the efficiency of Santomerse products, with and without various additions, in hard water and sea water. Washing tests were carried out by the "multiple suds" method on Indian Head fabric soiled with a standard soil, and the degree of soil removal was measured by means of the Lange photo-electric photometer. In general increasing water hardness reduced detergative efficiency. A 0.8 per cent. concentration of Santomerse No. 1, and a 0.32 per cent. concentration of Santomerse No. 3 produced optimum results in extremely hard water. These percentage concentrations are of equivalent active ingredient content. Absence of sodium sulphate in the Santomerse No. 3 product results in increased detergency. Santomerse combined with trisodium phosphate, tetrasodium pyrophosphate, or a mixture of the latter with sodium acid pyrophosphate gave results superior to those obtained with Santomerse alone. Santomerse Nos. 1, 3, and 55 were found to be poor sea water detergents. Addition of soap increased detergent action. For optimum detergent results with 51-D-7 bar (tallow kettle soap + Santomerse No. 55) the pH should be as near to 10 as possible, and the concentration 2 per cent. Additions of tetrasodium pyrophosphate or sodium carbonate to Santomerse increased the detergent efficiency of Santomerse in sea water. A ternary combination of Santomerse, soap and tetrasodium pyrophosphate produced unusually low soil removal. C.

### PATENTS

**Improvements in or Relating to Laundry Washing Machines.** Baker Perkins Ltd., F. Dewhurst and J. E. Pointon. B.P.558,456. App. 23/12/41. Acc. 6/1/44. It is stated that rotary washing machines either of the normal or end loading type suffer from constructional defects, including lack of rigidity, liability to leakage at the joints and bearings, undue wear and considerable maintenance costs. The new design aims at reducing these defects to a minimum and at the same time producing a neat machine in which excrescences such as pipes, pipe mountings, brackets and the like, are eliminated or reduced to a minimum. The use of an external trunnion drive and the penetration of the casing and end portions or heads by trunnions is avoided. The outer casing is in two parts which are connected by vertical flanges at the centre of the machine or other position, or by horizontal flanges. Each part consists of a head or end portion, having a hollow supporting base which can be bolted to the floor and a horizontal cylindrical or barrel portion. A dip gauge is provided by fitting a glass window to part of the casing at one end. The bearings are contained in the two head portions of the machine and the main driving pinion is integral with one end of the cage so that the driving mechanism or part of it actually rotates in the wash liquor. The drive is by an individual motor through reduction gearing housed in a suitable casing. Conduits are disposed within the casing so that water is supplied simultaneously through both hollow trunnions of the cage. A charging hopper is fitted for introducing the washing solutions,

and it is connected to a longitudinal conduit in the barrel portion. Steam is admitted through steam inlets in the bottom of the casing. La.

**Phosphatic Water Glass Detergents: Preparation.** Diamond Alkali Co. U.S.P. 2,333,443/4. (1) Alkali metasilicate with 2.9 mols. of water of hydration is melted and mixed with dry alkali pyrophosphate. The composition, containing 5-40 per cent. of the pyrophosphate, is cooled and ground to a dry powder. (2) A similar product contains 25-40 per cent. of Na tripolyphosphate. C.

## 8—BUILDING AND ENGINEERING

### (A)—CONSTRUCTION AND MAINTENANCE OF BUILDINGS AND PLANT

**Cotton Fabrics: Use in Laminated Plastics.** *Textile Research*, 1944, 14, No. 1, 11-14. A discussion of the use of cotton fabrics in the production of laminated plastics, the advantages and disadvantages of cotton fabrics compared with other materials, such as paper and fibreglass fabrics, for this purpose, and the need for the development of new fabric constructions especially suited to specific needs and for investigations of factors governing fabric strength and their relationship with the strength obtained from a fabric when used as a filler in a laminated plastic. C.

**Ground Plastic Spools: Production.** P. G. Weiller. *Machinist*, 1944, 88, No. 1, 97-98. A method for the production of Bakelite spools by wet grinding is described. Laminated Bakelite is received in the form of round bars  $1\frac{1}{2}$  in. in diameter which are first ground to final diameter in a conventional centreless grinder. A 0.001 in. tolerance is easily kept. The bars are cut into short lengths, sufficient for five spools, and fed to a specially designed grinder. A steady stream of water flows through the machine and keeps the wheels and work covered during the grinding. As the work emerges there is no change in the outside diameter. Sloping heads of the spools are kept within 0.0005 in. tolerances. The grinding wheels also form a 0.015 in. high shoulder on the inside of each of the spools. The machine is fully automatic and produces approximately 30 bars of 5 spools per hour. Spool blanks come from the grinder joined by a quill, which is then broken, as from this point on the blanks are handled individually. Blanks are placed in a special collet on the turret lathe, where the centre hole is drilled and the wheel head hollowed out. For the final operation, the spools are placed in two fixtures, one for grinding slots across the head and another for grinding slots parallel to the spool's axis. The spools are always covered by water except during the lathe operation. Dimensions remain stable in storage. The spool increases in diameter about 0.001 in. during the entire operation. As this increase remains stable machine settings are adjusted to compensate. C.

**Plastics: Use in Post-war Building.** H. H. Lusty. *British Plastics*, 1944, 16, 55-60, 116-118. Thermo-plastic and thermo-setting plastics and their physical characteristics are briefly described and the manufacture and uses of moulded plastics and sheet plastics are discussed. Possible developments in the use of plastics for windows and frames, wall and floor tiles, plumbing systems, and interior decoration are outlined. The development of synthetic resin-bonded plywood and its use in the manufacture of prefabricated houses are discussed. C.

**Reinforced Laminates and Plastics Heater Panels.** Reinforced Plastics Ltd. *British Plastics*, 1944, 16, 97-102. Armoured reinforcing material comprising a fabric having cotton and 24 high-tensile steel wires to the inch in both warp and weft is being used as a core in laminated paper and fabric materials to which it imparts high strength, high resistance to impact and shattering, and dimensional stability. This reinforcing material has also been applied to resin-bonded plywood and moulded plywood construction, to give increased strength and dimensional stability. Possible post-war applications of such reinforced materials, e.g. in the construction of railway rolling stock, are briefly discussed. For the construction of "Yarworth" electric panel heaters resistance wire is woven into fabric and fro in the form of loops, the ends being eyeleted to give good terminal connections. The whole is then impregnated with phenol-formaldehyde resin and pressed between a laminated paper material, resulting in a flat flexible sheet about  $\frac{1}{8}$  in. thick and weighing approximately 3 oz. per sq. foot, possessing a hard, glossy surface. The panels may be used as bed warmers and for other domestic and similar purposes. Panels can be fitted into

ceilings, walls, etc. Similar panels can be used as electric heating mats for cars, buses and rail coaches. They are non-inflammable, waterproof and non-corrodible. C.

**Wood: Glueing.** W. Gallay and G. G. Graham. *British Plastics*, 1944, 16, 50-54, 103-112; *Modern Plastics*, 1944, 21, No. 6, 126-129, 168-172. Laminated wood and plywood, and adhesives used in their production are discussed. Present glueing procedures are reviewed and the application of high frequency heating is considered. Details are given of a new glueing process in which a synthetic resin adhesive is used in conjunction with acetylene black or other highly conductive black so that the glue line is rendered conductive. Electrodes are placed at the edges of the glue line and a low voltage current of ordinary characteristics, e.g. direct current or 60 cycle A.C., is passed through the glue line. Rapid heating is obtained directly in the adhesive, and the latter is thus conveniently and efficiently hardened. The preparation and application of glue-black dispersions, the use of a carrier such as mesh fabric for the black or for the black and resin glue, the use of unsupported resin-black films, types of resin glues used, current characteristics, the proportion of conductive black, the dimensions of assemblies, time of glueing, electrodes, pressure, temperature and moisture content of wood, equipment, power requirements and efficiency and the quality of the glue line are discussed. Promising results in large scale trials are reported, various applications are discussed, and the advantages of the new glueing process are pointed out. C.

**Ethylcellulose Plastic: Extrusion.** *Modern Plastics*, 1944, 21, 132-134, 180. Ethylcellulose is one of the easiest plastics to extrude. Type ER is used for most applications, whilst type ELT is of exceptional value where extremely low temperatures are encountered. Type ELT also has somewhat better heat resistance than the ER type of material. Extruded tubing, strips and complicated shapes are very durable owing to the inherent mechanical strength and toughness of the plastic. Extruded products normally have a smooth, glossy surface, but it is possible to get matte finishes and retain good mechanical properties. Ethylcellulose plastic should be dried prior to extrusion since the absorption of even a small amount of moisture in storage or in transit is apt to result in a poor extruded section. Drying in a hot-air or infra-red oven at 80 to 90° C. for one hour immediately before extruding is ample for all grades. The temperature of the plastic mass as it comes from the die should be in the range 340-400° F. It is suggested that the plastic extrusion machine should have at least three, and preferably four, individually controlled temperature zones. The extruded plastic may be taken from the machine either by conveyor or by draw rolls. In the extrusion of ethylcellulose tubing, air is required to inflate the tubing during the cooling period. Ethylcellulose can be extruded to very close tolerances, the variation being of the order of  $\pm 1$  per cent. Dies should be 10 to 25 per cent. larger than the plastic section to be extruded and the piece drawn to the proper size by suitable adjustment of the speeds of the extruder and take-off mechanism. A list is given of some of the properties of representative extrusion grades of ethylcellulose (Ethocel) plastic. A wide variety of colours is available in transparent, translucent and opaque types. C.

**Plastic Laminates and Plywoods: Use in Aeroplane Construction.** Y. I. Zhibitskiĭ. *Aviapromyshlennost*, 1941, No. 4, 2-5 (through *Khim. Referat. Zhur.*, 1941, 4, No. 7-8, 116 and *Chem. Abstr.*, 1944, 38, 809). Plastic building materials are prepared by saturating fabrics (Textolite) or paper (Hetinax) with resin, drying and compressing at 120-150° and a pressure of 70-120 kg./sq. cm. The heat capacity of Textolite is one-third and its thermal conductivity  $\frac{1}{10}$ - $\frac{1}{15}$  of that of metal. Textolites with tensile strengths of 18 kg./sq. mm. and a Young's modulus of up to 1700 kg./sq. mm. have been obtained. A 1.5-3.0 mm. layer of Textolite is placed on steel parts. Bakelite plywood is used to cover the wings and fuselage of aeroplanes. Plastics from phenol resin and cellulose dust are used for the construction of sections of wings. Other substances used in the construction of aeroplanes are: a composition from asbestos fibres, kaolin and phenol resin (Absolite); a composition from asbestos ribbon, thin copper or brass net and phenol resin; a stratified plastic composed of asbestos fibres and phenol resins (Asbotextolite). Viamiz, a porous protein plastic of density 0.1 that of felt, is used as sound-insulating material. C.

**(C)—STEAM RAISING AND POWER SUPPLY**

**Boiler Flue Gases: High Dew-point Temperatures.** W. F. Harlow. *Engineering*, 1943, 156, 497-500. Difficulties brought about by acid deposits in the air heaters and economisers of certain modern boiler plants fired by mechanical stokers are due to abnormally high dew-point temperatures of the flue gases caused by excessive sulphur trioxide content. The results of tests in which flue gases were passed over rusty mild-steel scrap show that iron oxide acts as a catalyst for the oxidation of the sulphur dioxide in flue gases, trioxide formation being greatest at temperatures of 1,100° F. "Parkerised" mild steel, nickel-plated mild steel and stainless steel also behaved as catalysts. With mild steel treated by the "Penetral" process (surface of steel converted to aluminium ferride) catalytic action was slight. Samples of external scales from super-heater tubes of two boiler plants burning Durham and Yorkshire coals, respectively, exhibited catalytic properties at high temperatures. Spraying with milk of lime while hot inhibited the catalytic action of iron oxide and super-heater scale. Observations in actual plants are discussed and it is suggested that catalysis due to scale is less important than that due to metal tube surfaces. The influences of temperature, sulphur content of fuel, and steam content of flue gases are discussed. It is suggested that the immunity of pulverised-fuel plants from the troubles studied is due to coating of the heating surfaces with fine dust.

C.

**High-pressure Power and Low-pressure Process Steam Plant.** *Engineer*, 1944, 177, 273-275, 292-294. A detailed description and diagrams are given of plant designed to supply all the power and steam requirements of a large mill operating 24 hours per day, seven days a week, and requiring an electrical output varying from 4000 to 6000 kW, and a process steam output up to 120,000 lb. per hour. The plant includes three mono-tube steam generating units of 65,000 lb. per hour normal full-load capacity, operating at a pressure of 1400 lb. per sq. in., two 3300 kW geared turbo-generators, operating at 1325 lb. per sq. in. and a 4000-kW turbine, heat exchanger plant, high-pressure feed pumps, coal-handling plant, and feed-water arrangements. Operational data relating to analyses of turbine blade deposits, feed-water control, the method of starting up and shutting down the plant, and boiler efficiency tests are presented and discussed.

C.

**Steam Storage Accumulators: Theory.** C. A. Geneve. *Engineering*, 1944, 157, 283-284. A theoretical study of the operation of the Ruth "pressure-drop" type of steam storage accumulator. Equations are deduced and an example is given of the calculation of the changes in the mass of water present with changes in pressure in individual steps of charging and discharging processes.

C.

**(D)—POWER TRANSMISSION**

**American Textile Mills: Electrification.** W. W. Chase. *Textile World*, 1944, 94, No. 1, 56-63. A review of 50 years' progress in mill electrification in the United States. The contrasts between the Columbia Mills in 1894 and 1944 are shown in a series of pictures. Recent developments in other mills are also shown, including electronic control devices.

C.

**Driving Belts: Maintenance.** *Silk and Rayon*, 1944, 18, 342, 442. Practical hints are given on measures to ensure minimum wear of belts, on mounting motors, and on testing the alignment of shafts. Suggested sizes of V-belts for various motor speeds and horse-powers are tabulated.

C.

**Fabric Bushings: Dimensional and Weight Changes in Oil and Water.** R. Nitsche. *Kunststoffe*, 1943, 33, 11-14 (through Mark & Proskauer's *Resins, Rubber, Plastics Abstr.*, 1943, Sheet C; 171.3/816). A report is given of a study of dimensional and weight changes of hard fabric bushings of cotton and cellulose fabric when subjected to prolonged treatment in oil and in water, with and without oil pre-treatment at 100° C. The bushings were made from hard tubing composed of fabric and cresol resin. Tests were made of bushings which had been pressed into a steel collar and of bushings not so mounted. The bushings were held at room temperature for about a year in water or in spindle oil, and the changes in dimensions and weight determined. The results show that the dimensional and weight changes may be two or three times greater for impregnated cotton fabric. The behaviour of bushings appears to depend to a greater

degree upon the resin content than upon the degree of compression. Bushings from tubing which is coiled but not compressed behave better under the influence of oil and water than those from compressed tubing in so far as the resin content is actually higher. Pre-treatment in oil at 100° C. for 7 days effects only temporary improvement in the behaviour of bushings under the influence of oil and water. Conclusions as to the behaviour under oil and water of bushings pressed into a steel collar may be drawn from the results obtained from bushings not so pressed. Short-time tests at room temperature for the determination of the influence of oil and water are misleading, but tests at elevated temperature and pressure give excellent agreement with prolonged tests at room temperature.

C.

**V-Belt Drives: Selection.** H. A. Wilson. *Machinist*, 1944, 87, No. 51, Reference Book Sheet. An Econograph sheave selector chart is presented that enables designers to solve for six variables and determine an economical drive with the fewest V-belts. Advantages of using the largest sheave diameter permissible for a given belt cross-section, consistent with maximum space that can be allowed for the drive are pointed out. The chart gives five families of horse-power curves. Each family of curves gives horse-power at various velocities for a given cross-section of belt when running over stock sheaves ranging from the smallest that will not cause excessive heating to the largest at which no further gain can be realized in power transmitted. The curves show that horse-power capacity of a given cross-section of belt increases with sheave diameter and belt velocity. Totalizing lines for horse-power ratings of standard squirrel-cage motors are superimposed on the chart. In addition, motor-speed lines are drawn through velocity and sheave diameter points. The use of the chart is explained.

C.

**Asbestos Friction Materials: Characteristics.** R. T. Halstead. *Paper Trade J.*, 1944, 118, *TAPPI*, 74-77. The application of friction material to a rotating mechanism is discussed and it is pointed out that the chief result is a conversion of energy of motion into heat energy which in cases of severe service may result in operating temperatures of 1000° F. A suitable material must have a sufficiently high coefficient of friction to perform satisfactorily at all operating temperatures, must not wear too rapidly, and must not abrade the opposing metal surface too rapidly. Coefficients of friction and rate of wear data for standard types of friction materials against various metals are presented and discussed. Other necessary characteristics of friction materials are outlined. The advantages of asbestos for use in friction materials are pointed out and the functions of bonding media, such as rubber and resins, and friction modifiers, such as metals and carbonaceous materials, are discussed.

C.

#### (G)—HEATING, VENTILATION AND HUMIDIFICATION

**Electronic Heating Devices: Industrial Applications.** G. C. Nonken. *Paper Trade J.*, 1944, 118, *TAPPI*, 59-61. The electronic heating of electrical non-conductors is accomplished by placing the materials between plates to which voltages are applied at frequencies of up to 30,000,000 cycles per second. High-frequency electronic oscillators which draw power from any standard alternating-current power source are used. Fundamental equations which are used to predict the size and type of equipment needed are given, and various theoretical and practical considerations are discussed. High-frequency heating has been commercially applied to plywood bonding, the laminating of other thick wooden structures, the pre-heating of plastic preforms prior to moulding, and similar operations where the material to be heated is thick and the time to heat short. Electronic heating of thermo-setting resin-bonded paper plate stock during the curing process is discussed and power factor data are given.

C.

**Infra-red Radiation: Use for Evaporation and Distillation.** J. A. Reavell. *Industrial Chemist*, 1944, 20, 119-130. Types of infra-red generators are briefly described and wave length, temperature, energy and cost considerations are discussed. Applications of infra-red radiation for heating and drying are mentioned. The evaporation and distillation of liquids is studied and infra-red heating is contrasted with methods using steam, heated fluids or hot gases. Conditions of heat transfer in evaporators are examined. Infra-red evaporators designed for use in the laboratory are shown in photographs and diagrams. Satisfactory results obtained in the concentration of various sensitive solutions are reported.

C.

**High-velocity Air Stream: Temperature Measurements.** H. C. Hottel and A. Kalatinsky. *Instruments*, 1944, 17, 40-42. In selecting a method for measuring temperatures in high-velocity streams, the choice has to be made between probes designed to record the true temperature, probes to record the stagnation temperature, and conventional probes accurately calibrated for recovery factor. Since any stationary probe retards the gas in its immediately vicinity, measurement of true temperatures with ordinary probes is not possible. Stagnation temperature measurements have the advantage of yielding more representative data with respect to energy conditions and, in many cases, with respect to heat transfer than intermediate readings obtained with a calibrated conventional probe. The principal advantage of a stagnation probe lies, however, in the considerably improved reproducibility of calibration results. Tests of various probes are reported. A diagram of the equipment is given. The Pratt & Whitney high-velocity stagnation temperature probe was found to be satisfactory for precision measurements. For measurements which do not justify the use of special stagnation probes, the recovery characteristics of commonly-used bare wire thermocouples were investigated. The results indicate that bare wire thermocouples can be used for the great majority of measurements at velocities below 300 ft./sec. C.

**Spectroscopic Hygrometer.** L. W. Foskett and N. B. Foster. *Bull. Amer. Meteorological Soc.*, 1943, 24, 146-153 (through *Sci. Abstr.*, 1943, 46 A, 247). A simple grating spectrophotometer is used with a tungsten filament lamp and projector to measure the precipitable water in the atmosphere. Use is made of the  $1.380\mu$  water-vapour absorption band and the  $1.250\mu$  region for reference. Vacuum thermocouples and high-sensitivity galvanometer are used for energy measurement. Calibration tests were conducted over optical paths of 1.5-52 m. C.

#### (H)—WATER PURIFICATION

**Water Treatment Plant: Maintenance.** H. Nix. *Textile World*, 1943, 93, No. 4, 134-135. Practical hints are given on the maintenance of the motors, pumps and equipment for feeding chemicals of a mill water treatment plant. C.

**Lead: Attack by Water.** E. A. G. Liddiard and P. E. Bankes. *J. Soc. Chem. Ind.*, 1944, 63, 39-48. A critical survey is made of published information and an account is given of a study of the action of distilled water containing known quantities of carbon dioxide on lead, the effects of various additions to the water, electron diffraction examination of films formed on the lead, and the action of various natural waters on lead. The results obtained lead to the conclusion that oxygen plays an essential part in the dissolution of lead by water, the first stage being oxidation of the lead to lead oxide with subsequent formation of lead hydroxide in solution. In distilled or very soft water, containing only traces of carbon dioxide, the first effect on lead is a comparatively heavy attack with the formation of a white precipitate of basic lead carbonate in the water, probably formed by interaction of lead hydroxide with small amounts of carbon dioxide in solution. In time this reaction tends to be suppressed owing to the formation of an insoluble film of basic or normal lead carbonate on the surface of the lead. The formation of this protective film is accelerated by circulation of the water or by increase in the amount of carbon dioxide in the water. The amount of lead going into solution is, however, increased with increase in carbon dioxide content of the water, probably owing to the formation of lead bicarbonate. The presence of sodium or calcium bicarbonate in solution in the water favours the formation on the lead surface of a film which is completely protective even in the presence of carbon dioxide, provided the water is free from chlorides. As little as 40 parts of calcium bicarbonate per million is sufficient to inhibit attack by distilled water containing substantial quantities of dissolved carbon dioxide. The attack on lead by distilled water or bicarbonate solutions, both containing free carbon dioxide, is increased by the addition of sodium chloride. Addition of calcium sulphate to distilled water or solutions of bicarbonate has no effect, and chlorination of distilled water or public supply water has no marked effect on the action of the water on lead. The initial action of distilled water or soft water containing only traces of carbon dioxide can be suppressed by pre-exposure of the lead to solutions of calcium or sodium bicarbonate, but such films have no permanent protective action on waters containing appreciable quantities of carbon dioxide.

Protection against initial attack can also be obtained by pre-treatment with sodium silicate or sodium sulphide. Treatment with solutions of phosphates, sulphates and sulphites gives no initial protection. C.

#### PATENTS

**Dust Removing Appliance.** Dallow, Lambert & Co. Ltd. and J. E. Dallow. B.P.559,827 of 7/1/1943:7/3/1944. An appliance for removing dust and other impurities from manufacturing operations, comprises a nozzle applied to a tubular arm universally jointed with a pipe or duct and connected with a suction fan or blower, and a rigid support which serves to carry the pipe or duct and is fixed either directly or through an intermediate part upon a floor or the ground. In conjunction with this appliance there is used a suction fan which forms part of a unit including a separator or filter for separating the dust or other impurities from the air. The tubular arm is preferably telescopic and the nozzle is preferably jointed to the arm so that it can be adjusted to various angular positions. C.

**Cation-exchange Materials: Preparation and Use.** Permutit Co. Ltd. and E. L. Holmes. B.P.559,941 of 10/9/1941:13/3/1944. Cation-exchange materials consisting of sulphonated carbonaceous materials such as coal, peat, cellulosic substances, starch, sugar and related products, tar, fats, etc., or sulphonated synthetic resins of the phenol-aldehyde type are heated with an aqueous solution of a sulphiting agent to increase the cation-exchange capacity. The sulphiting agent may be a sulphite, bisulphite or metabisulphite. Resins are preferably treated at temperatures of 110 to 150° C. With sulphonated carbonaceous materials the best results are obtained by treatment with sodium metabisulphite at temperatures of 120-125° C. The products may be used for the treatment of water or other liquids. C.

**Low-density Fibre Board: Production.** Minnesota and Ontario Paper Co. U.S.P.2,332,369. A suspension of fibre is mixed with waste lignocellulose cooking liquor and the pH is adjusted to the iso-electric point. The mass is then agitated and aerated so that a stable foam is developed. The mass is made into a structural unit and dried. The material has a density of about 12 oz. to 5 lb. per cubic foot. C.

**Ferrous Metals: Protection against Corrosion.** E. I. Du Pont de Nemours & Co. U.S.P.2,333,206. The metal is coated with an alkylamine of at least 8 C atoms at the rate of 1 lb. per 10,000-80,000 sq. ft. of surface. The process may be applied to oxidised surfaces of ferrous metals after pre-treatment with phosphoric, chromic, molybdic or oxalic acid or one of their acid salts. C.

**Waxed Glass Fabric Liner and Gasket Sealing Material: Production.** Merck and Co. Inc. U.S.P.2,333,535. A tightly woven glass fabric having fibres of about 0.00025 inch diameter and weighing about 1.4 lb. per sq. yd. is impregnated with 40-75 per cent. by weight of wax. The unwaxed fabric is specified as having an air permeability of about 30 cub. ft. per min. per sq. ft. under 1 inch water pressure, and water permeability of about 286 gallons per minute sq. ft. under 10 lb. water pressure per sq. inch. The wax has a viscosity of 62.7 seconds at 210° F., melting point 170° F., and needle penetration of 0.12 cm. at 77° F., and is free from carbonizable matter, free fatty acids, esters, odour or taste. C.

### 9—PURE SCIENCE

**Insect Pests: Control by Fumigation.** E. A. Back and R. T. Cotton. U.S. Dept. Agric. Circ. No. 369, 1942, 63 pages. An illustrated review of general mill or warehouse fumigation; the use of vaults for fumigating products, e.g. clothing; vacuum plant for tobacco, sweets, etc.; and fumigation of specific products. The toxic agents used and their production are described. Respirators should be worn in most cases and first-aid measures in case of accidents with prussic acid are set out. C.

**West Indian Dry-wood Termite: Control.** G. N. Wolcott. *Caribbean Forester*, 1943, 4, 145-157 (through *Tropical Agriculture*, 1944, 21, 14). The West Indian dry-wood termite, *Cryptotermes brevis* (Walker) is able to live in dry wood within houses and does not construct exposed nests. West Indian mahogany is unpalatable to this termite. When small samples of the very susceptible wood

of *Bursera simaruba* were dipped in solutions of various inorganic compounds and then made available to the termites, along with untreated mahogany and other woods of known susceptibility, samples dipped for 10 min. in a solution of approximately half an ounce of either copper sulphate, zinc chloride, barium chloride, or cadmium nitrate per gallon of water became more resistant to attack than mahogany. Treatment of new furniture with such solutions previous to painting or varnishing would provide cheap protection. Since arsenic is toxic but not repellent, the introduction of a 0.3 per cent. arsenic solution into the tunnels of infested wood might not only kill the present colony but prevent reinfestation. C.

**Air Sampling Flowmeter.** H. M. Lemon and H. Wise. *Science*, 1944, 99, 43-44. A small flowmeter designed to be attached to the upstream end of any air sampling device is shown diagrammatically. A constricting orifice, 4 mm. inside diameter and 10 mm. long, in a tube 6 mm.  $\times$  48 mm. gives a satisfactory change in static pressures for air flows between 0.33 and 1.30 cu. ft. per min. This change in static pressure is measured by a glass manometer (4.5 mm. inside diameter and 120-150 mm. long) filled either with water or a 1 per cent. solution of a suitable detergent with a few drops of phenol red added for colouring; the detergent inhibits mould growth and improves the wetting of the glass. Graph paper ruled in millimetres backed by a wooden tongue depressor blade and bound to the manometer with transparent cellulose tape provides a simple scale. Any non-corroding metal or chemically inert plastic, such as Plexiglas, may be used in the construction of the flowmeter. For calibration, the flowmeter should be attached upstream to a standard wet-gas meter or a previously calibrated Venturi meter. C.

**Automatic Acidity Recording Apparatus.** *Silk and Rayon*, 1944, 18, 331-332. An account is given of an automatic titration unit with the following main features. The sample to be titrated is arranged to discharge itself into a beaker, fitted with stirring apparatus and standing on a revolving table, at regular intervals (say, every 3 minutes). It then closes a circuit which releases a spring to open the burette tap. The standard solution flows in until a colour change occurs, whereupon a thalofide cell causes the tap to be turned off. A beam of light is then momentarily operated by means of a shutter to project the image of a float in the burette on a calibrated film. The film is run through a developer, actuated by a time-lag, and gives burette readings in white on a dark background. The burette then fills again and the contact of the float at the top shuts off the feed. A pump empties the beaker. C.

**Glass Electrode Valve Amplifier.** Chun-yu Lin. *J. Sci. Instruments*, 1944, 21, 48-49. A simple valve amplifier for measuring glass electrode potentials is described and shown diagrammatically. The system is characterised by high gain of voltage amplification, great flexibility and economy of power supply. C.

**Titrimetric Analysis Solutions: Standardisation; Volume Measurements.** W. M. Thornton, Jr. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 50-53. Factors influencing the accuracy of measurements of volume, particularly the effects of the thermal expansion of liquids are discussed. Burettes designed for accurate measurements are described and calibration data are given. Procedures for the standardisation of potassium permanganate, borax, and sodium hydroxide solutions are outlined and experimental data showing the high degree of accuracy obtainable are presented. C.

**Iron: Determination.** J. L. Henry and R. W. Gelbach. *Ind. Eng. Chem. Anal. Edn.*, 1944, 16, 49. Potassium dichromate, with diphenylamine sulphonic acid as indicator, can be used in place of ceric sulphate in the determination of iron by the Walden silver reductor method. Hydrochloric acid (1N.) is used instead of sulphuric acid. Details of the procedure and results showing the effects of added impurities are given. Mn, Cr and Ti do not interfere and V does not interfere in concentrations of 100 mg. or less in 200 ml. of titrating solution. C.

**Mahogany Soaps: Adsorption Analysis.** J. M. Koch. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 25-28. For the analysis of mixtures of petroleum oil and oil-soluble sodium sulphonates (mahogany soaps) produced in the manufacture of medicinal white oil, a sample is dissolved in petroleum naphtha and the solution passed through a column of Attapulugus clay. The oil is carried through by

the naphtha and can be weighed after evaporation of the solvent. The sulphonate adsorbed by the clay is removed by washing with methyl alcohol and weighed after evaporation of the latter. Any resinous material in the sample is also adsorbed by the clay from which it can be removed by the use of ethyl acetate or diethyl ether before the treatment with methyl alcohol. Alternatively, if it is only necessary to determine the sodium sulphonate content and the total amount of oily or inactive matter in the sample, a suitable resin eluant may be used as solvent in place of the petroleum naphtha and the oil and resin determined together in the first percolate. The results of analyses of mixtures of known composition show that the method gives accurate results. C.

**Pectin: Determination.** E. F. Bryant, G. H. Palmer and G. H. Joseph. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 74-76. Details are given of an improved pentose-furfuraldehyde method for the determination of pectin in biological materials which involves steam distillation from 85 per cent. phosphoric acid and determination of the furfuraldehyde in the distillate by the aniline acetate reaction. Colour measurements are made with the photo-electric colorimeter or the Duboscq-type colorimeter. C.

**Pectin and Pectic Acid: Determination by Electrodeposition.** K. T. Williams and C. M. Johnson. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 23-25. Details are given of a procedure and apparatus for the determination of soluble pectin in which the solution is freed from electrolytes by the use of ion-exchange resins and is then subjected to electrolysis so that the pectin is deposited at a platinum anode in a weighable form. Results obtained in the analysis of fruit extracts are presented. The results obtained are higher than those obtained by the calcium pectate method. Pectic acid in fruit extracts can be determined by electrodeposition after subjecting the extracts to acetone purification and hydrolysis and removing the electrolytes. C.

**Phenol and Cresols: Identification.** W. B. Deichmann. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 37-38. Qualitative tests employing ferric chloride, hypochlorite, and the reagents of Melzer, Millon, Liebermann, Guareschi, and Cotton are described. A single test or a combination of several of these colour tests can be used for the identification of phenol or *o*-, *m*-, or *p*-cresol, if the unknown solution contains only one of these compounds. C.

**Amorphous Cellulose: Determination by Thallous Ethylate Method.** A. G. Assaf, R. H. Haas and C. B. Purves. *J. Amer. Chem. Soc.*, 1944, 66, 59-65. Cotton linters, highly swollen in caustic soda and dried through methanol and benzene, were immersed in a large excess of 0.1N. thallous ethylate solution. The thallium cellullosate so formed was methylated with excess methyl iodide in benzene. The methoxyl content of the product was accepted as proportional to the percentage of the cellulose wetted by the particular liquid in which the thallous ethylate was dissolved. The extent of the methylation did not depend upon the molecular volume of normal hydrocarbon solvents for the thallous ethylate, but the relationship was inverse and linear for the normal ethers from diethyl to di-*n*-amyl. Branched chain or cyclic ethers and hydrocarbons penetrated the cellulose less efficiently than their normal analogues and thallations in alcohols, although reproducible, were thought to be incomplete. Amorphous cellulose was defined as the percentage wetted by an ether of zero molecular volume and was estimated by extrapolating the linear methylation-molecular volume plots of three or more straight-chain ethers. An extrapolation of the similar plot for the normal alcohols from ethyl to hexyl tended to confirm the result, which was probably within  $\pm 10$  per cent. The amorphous fractions of swollen linter samples were as high as  $27 \pm 2$  per cent., but the amount present in unswollen fibres was of the order of 0.25 to 0.5 per cent. The corresponding colloidal surfaces, ranging from  $520 \times 10^4$  to  $5$  or  $10 \times 10^4$  sq. cm. per g., were not inconsistent with published estimates based upon other experimental methods. C.

**Cuprammonium Cellulose and Glucoside Solutions: Optical Rotation.** R. E. Reeves. *Science*, 1944, 99, 148-149. The high (laevo) optical rotation of cellulose in cuprammonium hydroxide solution is believed to be a property of a complex formed by a copper-containing radical and free hydroxyl groups of cellulose.  $\beta$ -Methyl glucoside dissolved in cuprammonium hydroxide solution is not laevo-rotatory but  $\beta$ -methyl-4-methyl glucoside, which possesses the same

free and substituted positions as cellulose, shows optical activity remarkably like that of cellulose. Observations with other methylglucosides substituted in various positions indicate that free hydroxyl groups in positions 2 and 3 and substitution in position 4 are essential for complex formation. The lævo-rotatory complex appears to be a cyclic structure involving hydroxyl groups on glucose carbon atoms 2 and 3. C.

**Corn Stalks: Oxidation with Alkaline Nitrobenzene.** R. H. J. Creighton and H. Hibbert. *J. Amer. Chem. Soc.*, 1944, **66**, 37-38. Oxidation of corn stalks by nitrobenzene and alkali gives, as actual pure products, vanillin, syringaldehyde and *p*-hydroxybenzaldehyde in yields of 4.5, 2.6 and 1.4 per cent., respectively, based on the Klason lignin content of the corn stalks, the crude yields being 5.3, 3.2 and 1.8 per cent. This represents the first isolation of free *p*-hydroxybenzaldehyde from lignin. Its presence may serve as a distinguishing characteristic between the mono- and di-cotyledons. C.

**Lignin-type Substances: Oxidation with Chromic Acid.** W. S. MacGregor, T. H. Evans and H. Hibbert. *J. Amer. Chem. Soc.*, 1944, **66**, 41-44. Chromic acid oxidation of oxygenated side-chain phenylpropane derivatives related to lignin yielded 80 to 95 per cent. of the theoretical amount of acetic acid thereby providing a method for the determination of —CMe groupings in such products. Oxidation of spruce and maple woods showed that the native lignin present in each wood does not contain an appreciable quantity of end methyl groups. A difference between extracted, amorphous spruce and maple ethanol lignins was observed, in that the former was found to contain an appreciable quantity of —CMe groupings (one for each four or five  $C_6-C_3$  units) whereas the latter contained few or no such groups. Repeated ethanolysis of spruce ethanol lignin effected an increase in the proportion of terminal methyl groups. Strong experimental support is thus found for the theory that native lignin is characterized by the absence of terminal methyl groups and that their presence in extracted lignins is the result of intramolecular changes undergone by very reactive side chains such as are present in hydroxyconiferyl alcohol. C.

**Plant Materials: Taxonomic Classification by Oxidation with Alkaline Nitrobenzene.** R. H. J. Creighton, R. D. Gibbs and H. Hibbert. *J. Amer. Chem. Soc.*, 1944, **66**, 32-37. Alkaline nitrobenzene oxidation of 47 widely varying accepted forms of gymnosperms and angiosperms (including various types of wood, jute fibre, bamboo, rye straw and corn stalks) has shown that in practically all cases the former yield only vanillin, whilst the latter give both vanillin and syringaldehyde. The yields of vanillin, in the gymnosperms, vary between 15 and 24 per cent., based on the Klason lignin. With the angiosperms the combined yield of vanillin and syringaldehyde amounts to 35.51 per cent., the ratio of the former to the latter being approximately 1:3. Considering the highest combined aldehyde yield (silver maple 51 per cent.) obtained, this amounts to 61 per cent. of the Klason lignin based on the assumption that the native maple lignin is derived essentially from a mixture of anhydro polymeric forms of coniferyl and syringyl alcohols. Exceptions to the above ratio (1:3) of mixed aldehydes were found in the case of certain primitive angiosperms characterised by the absence of vessels, the ratio in this case being 1:1. All genera of the *Gnetales* (a group of uncertain position) gave both vanillin and syringaldehyde on oxidation, a result in harmony with their high lignin and methoxyl values and behaviour with the Mäule reagent. Their relationship to the angiosperms rather than to the gymnosperms is thus indicated. Only a very few members of the *Coniferales* were found to yield, on oxidation, an aldehyde mixture containing both vanillin and syringaldehyde and to give a definite Mäule reaction. The behaviour on oxidation of all the plants investigated is in complete agreement with their colour reaction (or its absence) when tested with the Mäule reagent, and thus offers a new chemical procedure for taxonomic classification. C.

**Starch Modification B: Structure.** R. E. Rundle, L. Daasch and D. French. *J. Amer. Chem. Soc.*, 1944, **66**, 130-134. Methods of preparing films and fibres of the "B" modification of starch are outlined and X-ray diffraction data are discussed. A unit cell with  $a_0=16.0$ ,  $b_0=10.6$ ,  $c_0=9.2$  Å. is found for the "B" modification. The structure is probably orthorhombic. A rough structure is proposed. It is pointed out that, in contrast to cellulose, the configura-

tion of the starch chain depends upon how the starch is treated and that plasticizers generally alter the starch structure considerably. C.

**Pyrodextrins: Structure.** B. Brimhall. *Ind. Eng. Chem.*, 1944, **36**, 72-75. Pyrodextrins are degradation products of starch obtained by roasting, either alone or in the presence of small amounts of catalytic agents. The properties of a commercial water-soluble pyrodextrin (a British gum) are described and shown to be in harmony with a molecule containing approximately 66 glucose residues arranged so that there are four or five short branches of approximately five glucose units each. The branched (amylopectin) and unbranched (amylose) components of corn-starch, as well as amylopectin, retrograded starch, and ordinary granular starch, have been dextrinized and the course of conversion has been followed by water solubility, reducing power, and digestibility with  $\beta$ -amylase. The results indicate that the linear portions of starch become branched during the heating process, as demonstrated by loss of ability to retrograde, increased resistance toward  $\beta$ -amylase, and percentage of tetramethyl-glucose upon hydrolysis of the methylated product. A possible mechanism for heat dextrinization is discussed. C.

**Amino Acids: Colour Reactions.** H. Tauber. *J. Amer. Chem. Soc.*, 1944, **66**, 310. Certain amino acids are converted to chromogens when heated. Alcoholic extracts containing these chromogens become more deeply coloured when alkali is added, but on subsequent acidification become colourless or much paler. *l*-Tyrosine, *l*-tryptophan, and *dl*-threonine turn reddish brown on heating, exhibit a light brown or reddish brown in alcoholic solution, become more deeply coloured on the addition of alkali and turn a light brown, or, with *l*-tyrosine, a yellow colour on acidification. *l*-Histidine mono-hydrochloride becomes light brown on heating, light yellow in alcoholic solution, deep yellow on the addition of alkali and almost colourless on acidification. *dl*- $\beta$  or *l*- $\beta$ -Phenylalanine and *l*-leucine on heating partially sublime, turn yellow and give a yellow or light yellow colour in alcoholic solution. This turns to a deep yellow on addition of alkali and becomes almost colourless on subsequent acidification. With the  $\beta$ -phenylalanines, the alkaline alcoholic solution exhibits a greenish-yellow fluorescence, which is particularly strong in ultra-violet light, without the addition of alkali. On heating, *l*-cystine, *l*-cysteine, glycine, *l*-hydroxyproline, *dl*-methionine, glutamic acid, *dl*-aspartic acid, *dl*-serine, *l*-proline, *d*-arginine mono-hydrochloride, *dl*-lysine and *d*-lysine change to yellow, brown or black decomposition products without chromogenic properties. *dl*-Alanine, *dl*-valine and *dl*-iso-leucine sublime completely leaving no pigment or residue. C.

**Antioxidants: Properties.** F. Bergel. *Chemistry and Industry*, 1944, 127-128. A discussion of the preparation, antioxygenic activity and other properties and uses of antioxidants of the quinol and pyrogallol groups, dienols,  $\omega$ -hydroxy-hydroxyacetophenones, and nitrogen-containing inhibitors. It is pointed out that quinols, pyrogallol and dienol derivatives have so far proved to be the most effective and practical stabilizers. C.

**Benzoquinone and Anisole Derivatives: Resonance Effects.** H. H. Hodgson. *J. Soc. Dyers & Col.*, 1944, **60**, 65-67. The melting point order and variation of colour of the 2-halogenbenzoquinones are interpreted on resonance theory, which also satisfactorily accounts for melting point regularity among the 3-halogenbenzoquinone-4-oximes. Benzoquinone-monoximes and their ethers always melt at higher temperatures than the tautomeric nitrosophenols and ethers, due to predominance of a more highly polarised resonance structure. The effect of fluorine in controlling the nitration of 3-fluoroanisole and of its mononitro-derivatives may be readily explained by resonance structures, and the argument thus developed is applied satisfactorily to the order of replacement of all three chlorine atoms by nitro-groups when 3-fluoro-2:4:6-trichloroanisole is treated with fuming nitric acid at 0° C. C.

**Dilinoieic Linear Superpolyesters: Preparation.** J. C. Cowan and D. H. Wheeler. *J. Amer. Chem. Soc.*, 1944, **66**, 84-88. Superpolyesters were prepared from the unsaturated dibasic acid, dilinoieic acid, with ethylene, decamethylene and hydrogenated dilinoieyl glycols. Loss and decomposition of ethylene glycol occurred at reaction temperatures and therefore superpolyesters from ethylene glycol were only obtained when excess of glycol was used and the final stages of the reaction were effected by glycolysis. Superpolyesters having molecular

weights of 20,000 or more were obtained by direct esterification when decamethylene and hydrogenated dilinoleyl glycols were used. A study of the variation of viscosity with molecular weight showed a straight-line relationship between log. viscosity and square root of molecular weight up to molecular weights of 10,000 on certain polyesters. Direct comparison of superpolyesters from dilinoleic acid and from hydrogenated dilinoleic acid demonstrated that reaction conditions can be controlled so that non-conjugated unsaturation does not cause cross-linking of chains. C.

**Unsaturated Fatty Acid Chlorides: Preparation.** T. R. Wood, F. L. Jackson, A. R. Baldwin and H. E. Longenecker. *J. Amer. Chem. Soc.*, 1944, 66, 287-289. Oleyl, elaidyl, linoleyl and linolenyl chlorides were prepared by the action of oxalyl chloride on the corresponding pure acids. Linoleic and linolenic acids and the corresponding chlorides were examined spectrophotometrically. The results demonstrate that the reaction of the acids with oxalyl chloride was not accompanied by rearrangements of the double bonds to produce conjugated systems. C.

**Cellulose: Electrokinetic Properties and Surface Conductivity.** Gertrude Rabinov and E. Heymann. *J. Phys. Chem.*, 1943, 47, 655-668. Experimental conditions and theoretical considerations affecting streaming-potential measurements with cellulose are discussed and a report is given of investigations of the electrokinetic properties and surface conductivity of purified cotton, cotton wool, oxycellulose, mercerized cellulose, and regenerated cellulose. The results show that in distilled water the  $\zeta$ -potential decreases and the surface conductivity increases with increasing carboxyl-group content of cellulose. Substitution of carboxyl H by Ca and Na lowers the surface conductivity, but affects the  $\zeta$ -potential little. A theoretical interpretation of these results is given. It is shown that a maximum observed in the  $\zeta$ -potential/concentration curve for alkali chlorides is not due to a dispersion of the surface conductivity. For uni-univalent and bi-univalent electrolytes the surface conductivity shows a marked increase with concentration whilst the  $\zeta$ -potential decreases. The difficulty of reconciling the increase of surface conductivity with a simultaneous decrease of  $\zeta$ -potential is pointed out, and two tentative explanations are suggested. C.

**Polyamide Solutions: Viscosity-Chain Length Relationship.** A. Matthes. *J. prakt. Chem.*, 1943, 162, 245 (through Mark & Proskauer's *Resins, Rubber, Plastics Abstr.*, 1943, Sheet C2:163). Polymers of  $\epsilon$ -aminocaproic acid with degree of polymerization below 50 were prepared by lactam polymerization in the presence of from 10 to 300 per cent. (on lactam) of water. For end group determination amino nitrogen was determined by the van Slyke method. Viscosities of 1 per cent. (by vol.) solutions in pure sulphuric acid and in 40 per cent. sulphuric acid were determined with the Ubbelohde viscometer. Solutions (1 per cent. by vol.) of technical fibres of  $\epsilon$ -aminocaproic acid polymers (Perlon L) in 40 per cent. sulphuric acid were heated to 50° C. for periods from 5½ to 184½ hours. The viscosity was measured at 20° C., and the degree of polymerization calculated by means of formulae obtained by correlating viscosity data with results of end-group determinations. The degrees of polymerization thus calculated were correlated with those to be expected from kinetic considerations. The results indicate the applicability of the parabolic relationship  $[\eta] = K \cdot P^a$  for the viscometric molecular weight determination of  $\epsilon$ -aminocaproic acid polymers, including the higher polymerized technical products. According to this equation, the degree of polymerization of Perlon L exceeds 200. The values found for the exponent  $a$  indicate that the polyamide molecules in solution are unbranched but highly curled. C.

**Starch-Iodine Complexes: Absorption Spectra.** R. R. Baldwin, R. S. Bear and R. E. Rundle. *J. Amer. Chem. Soc.*, 1944, 66, 111-115. Differences in the transmission curves of the iodine complexes of amylose and amylopectin materials and the possibilities of colorimetric analysis of starch for amylose and amylopectin are discussed. The amount of iodine bound in complex formation with amylose increases as the concentration of iodide decreases, becoming one iodine molecule for six glucose residues for infinitely dilute iodide solutions. The wave length of maximum absorption of an amylose-iodine solution shifts toward the red as the chain length of the amylose is increased. The shift is in the same direction when the lengths of the unbranched portions of amylo-

pectin are increased. An increase in the molecular extinction coefficient accompanies an increase in the length of amylose or an increase in the lengths of unbranched portions of amylopectin. Both these properties permit the relative evaluation of molecular weight of an amylose or degree of branching of an amylopectin, the change in molecular extinction coefficient being the more sensitive. Data and curves are given for iodine complexes of amyloses and amylopectins of different origins. C.

**Photo-electric Photometer.** J. McG. Sowerby. *J. Sci. Instruments*, 1944, 21, 42-45. Diagrams and a detailed description are given of a photo-electric photometer for measuring the light scattered at about  $45^\circ$  from the surface of a transparent plastic which has suffered abrasion. The abraded portion of the plastic is illuminated by a low-voltage lamp via a lens system, and the scattered light falls on a sensitive vacuum photo-cell coupled to an amplifier. The amplifier drives a tuning-eye whose shadow is always returned to a given mark, and the adjustable element is a scaled potentiometer. C.

**Colour Harmony: Geometric Formulation.** P. Moon and Domina E. Spencer. *J. Optical Soc. America*, 1944, 34, 46-59. A scientific development of the classical theories of colour harmony is presented. The qualitative ideas of artists and colour specialists are incorporated into a quantitative system depending on the C.I.E. colour specification and its transformation into a metric colour-space. The entire theory is based on two postulates: pleasing intervals and ambiguous intervals exist between colours, and an orderly geometric arrangement of colour-points leads to harmony. On this foundation is built a classification of harmonies and these harmonies are tabulated in some detail. The combinations are by no means equally pleasing, but elements of order can be discerned in all of them. Divisions into regions of similarity, ambiguity, contrast and glare are made which are in accordance with classical colour harmony, but the numerical designations of these regions are new and are based on preliminary experiments. The advantage of the method is that it gives the designer a wealth of new harmonies from which he can select the particular one best fitted to his needs. Classical colour harmony is confined to relations among colours, irrespective of area. In the present paper conditions are simplified to agree with classical theory. Areas are kept equal, adaptation is fixed at a neutral gray of Munsell value 5, and no attempt is made to compare the various harmonies aesthetically. C.

**Solids: Orthogonal Projection; Photographic Method.** P. Lake. *British J. Photography*, 1944, 91, 129-132. In examining fossils which have been distorted by pressure it has sometimes been possible to determine the amount and kind of distortion with considerable accuracy and to prove that an orthogonal projection of the distorted specimen would have the same proportions as the specimen had before distortion. The preparation by the ordinary methods of a drawing which will show the original form is laborious, and it has been found possible, without exceptional cameras or lenses, to obtain a photograph which would have the same proportions as the orthogonal projection. A detailed explanation of the method is given. C.

**Fine Particle Measuring Instrument.** Fisher Scientific Co. *Laboratory*, 1943, 14, 63-65. The determination of the size of particles of sub-sieve range in the Fisher "Sub-Sieve Sizer" is based on measurements of resistance to air flow by packed particles. A motor-driven air pump builds up pressure in a pressure regulator to a constant head so that a uniform flow of dry air passes through the packed powder sample. The flow of air is measured by means of a double range flow meter. The average particle size corresponding to the observed liquid level in the manometer is read directly from a chart. The range of measurements is from 0.2 to  $50\mu$ . C.

**Elastomers: Young's Modulus; Effect of Low Temperatures.** J. W. Liska. *Ind. Eng. Chem.*, 1944, 36, 40-46. Methods and apparatus are described for bending and brittleness tests at low temperatures. Data showing the variation with temperature in the range  $0^\circ$  to  $-60^\circ$  C. of Young's modulus for natural and synthetic rubbers are presented and discussed and the effects of freezing time are considered. The results indicate that extremely long test periods are required for the investigation of physical changes resulting from low-temperature crystallization. The rubber stocks having relatively high moduli at a given low

For disinfection the chlorophenols with the greatest application are the chloro-xenols, and *p*-chloro-*m*-xylenol has been widely used. Mixed chlorinated xylenols prepared from wider cuts of distillation products are available. These mixed products always contain a proportion of unchlorinated xylenols, but by careful manufacture the latter can be kept within the 1 per cent. tolerance for medicinal products. For the so-called non-poisonous disinfectants for sale through general channels, however, only pure *p*-chloro-*m*-xylenol or other legally non-poisonous substances can be used, in compliance with the law. C.

**Rot-proofed Fabrics: Free Copper Compound Contents.** O. A. Samsonova. *Tekstil. Prom.*, 1943, No. 1/2, 15-18 (through *Chem. Abstr.*, 1944, 38, 1120<sup>9</sup>). Impregnated fabrics may contain copper and chromium tannates, aluminium soaps, aluminium and iron tannates and copper soap. Further, the treatment is followed by a neutralising bath of a sodium carbonate solution, in consequence of which there is the opportunity for the formation of aluminium hydroxide and basic copper carbonate. The author investigated the formation of copper compounds. To simplify the problem, aluminium acetate was omitted. The following mixtures were prepared: (1) tannins, copper sulphate and dichromate, (2) basic copper carbonate, and (3) solutions of copper sulphate, dichromate and sodium carbonate. The reaction between the tannins and copper sulphate proceeds slowly and does not go to completion, whereas dichromate reacts completely. The reaction between copper sulphate and sodium carbonate proceeds rapidly and practically completely. When two baths are used, copper may form tannates, soap and basic carbonate. Of these the first two are not stable toward water-extraction, whilst the third is stable. If it is assumed that the reaction between the tannin and dichromate involves the oxidation of the tannin and reduction of chromium and that the reduced chromium forms the tannate, then the tests prescribed by the VTU (standards) would be always negative, since precipitation with lead acetate reveals only chromic salts. Results of studies on the effect of cleaning of the fabric on the formation and retention of free copper salts, and of the effect of solutions of copper salts on strength and ageing, are tabulated. Copper compounds are extracted with boiling water because of the insufficient stability of copper tannates and soaps and of combinations of copper and linen fibres. Therefore the greater the copper content in the fabric the more "free copper compounds" may appear. If the presence of appreciable quantities of free copper compounds is an indication of considerable copper fixed in the fabric, then the test is possible, since a large quantity of fixed copper in the fabric contributes to the strength and durability of the fabric. Actually no limit can be set for the amount of free copper compounds in a fabric since this limit would depend on the amount of copper applied to the fabric. C.

**Leather: Mildew Proofing.** R. M. Lollar. *J. Amer. Leather Chem. Assoc.*, 1944, 39, 12-24. An interim report is given of tests of the protective power of some 38 antiseptics (branded products and known chemicals) for leather in exposures to a mixed infection of moulds at 95-100° F. and 85-95 per cent. R.H. Patch tests were also done to check the possible danger of dermatitis due to wearing such protected leather. It is recommended to make field trials with 0.5 per cent. of *p*-nitrophenol and *p*-chloro-*m*-xylenol or *p*-chloro-*m*-cresol. Salicylanilide is said to merit further study. "Preventol I" (trichlorophenol in triethanolamine) is effective, but possibly harmful to leather because of its alkalinity. Organic mercury compounds are rather irritating to the skin. Sulphated castor oil appears to be a good vehicle for applying antiseptics to leather. C.

**Rubber: Use for Protection from Mustard Gas.** T. R. Dawson and R. W. Parris. *J. Rubber Research*, 1944, 13, 33-48. This report summarises published information on the manufacture of gas-protective material from rubber, rubber derivatives, synthetic rubber-like materials and non-rubber materials, types of gas-protective articles (gas masks, clothing, boots, and joint-sealing for gas-proof chambers), the behaviour of rubber towards mustard gas, methods of testing the permeability of rubber or other material, and the resistance of paints, specifications for the different types of gas-protective products, and the decontamination of tyres, electrical equipment, rubber and oilskin clothing and respirators, and leather. C.

**Sodium Borophosphate: Application in Flame-proofing.** *Silk and Rayon*, 1944, 18, 445. Sodium borophosphate is described as a clear, syrupy liquid that forms a thin, transparent film over a fibre and is an efficient flame-proofing agent. It is dissolved in water (1 pint to 6-11 pints of water, according to the fabric) for application in open tanks or a spray may be prepared from 17 lb. of the agent, 15 gallons of water, and 2 oz. of a wetting agent. C.

**Water-repellent Finishes: Use of Wax Emulsions.** J. V. Steinle. *Text. Col.*, 1944, 66, 11-12. A survey of the advantages of wax emulsions as water-repellent coatings for fabrics. They have been successfully combined with mildew-proofing agents. W.

#### PATENTS

**Fur: Carrotting.** The Non Mercuric Carrot Co. B.P.559,464 of 21/2/1944. A carrotting solution is mixed with neutral, highly-absorbent and powdered material which is non-reactive to the solution, e.g. sawdust, natural and synthetic ground sponge, powdered asbestos, etc. The powdered material is also mixed with penetrators, e.g. sand, ground or powdered abrasives, and ground stone, not containing carbonates. The concentration of the carrotting solution must be increased 30-50 per cent. over that used in the normal brushing method. The carrotting effect is improved by the addition to the solution of glue, gelatin or furfural. The carrotting mixture is applied to the skins by tumbling, with which drying may be combined; the dry material is mechanically shaken from the skins and recovered for further use. W.

**Fulling or Planking Machines, especially for Hat Bodies and Hats.** V. C. Böhm. B.P.559,675 of 1/3/1944. The number of points of contact and thus the production of a fulling machine is increased by allowing a main roller of greater diameter to co-operate with secondary rollers of smaller diameter arranged at an acute angle to one another, the hat bodies, etc., being fulled by the oscillating motion of the main roller at each point of contact with the secondary rollers. W.

**Delustred Cellulose Derivative Filaments and Films: Production.** British Celanese Ltd. B.P.560,375 of 27/7/1942:3/4/1944 (Conv. 9/8/1941). Filaments or films having a basis of an organic derivative of cellulose and containing polymerised ethylene oxide are subjected to the action of a hot aqueous medium until the desired loss of lustre has occurred. The polymerised ethylene oxide may be added in various amounts, e.g. 1-50 per cent., to the solutions from which the filaments or films are prepared. Delustering of filaments, or of yarns, fabrics or other textile products containing the same may be carried out effectively with water at elevated temperatures, and the aqueous delustering bath may also contain substances such as soaps, salts, acid salts, pine oil or tetrahydronaphthalene, which accelerate or enhance the delustering action. The delustred products show increased affinity for dyes and have excellent strength and crêpeing properties. C.

**Regenerated Cellulose Yarns and Fabrics: Treatment to Increase Capacity for Shrinking.** British Celanese Ltd. B.P.560,378 of 21/9/1942:3/4/1944 (Conv. 20/9/1941). Regenerated cellulose yarns obtained by stretching and saponifying yarns made of an organic ester of cellulose, or fabrics made from such yarns, are treated with a solution containing between 30 and 75 per cent. by weight of a mercerising agent, e.g. caustic soda, and then removing the solution from the treated materials. The treatment increases the capacity of the materials for shrinkage on drying and also improves their extensibility. C.

**Tertiary Amine Derivative Water-repellent Agents: Preparation.** G. M. Clark (Warwick Chemical Co., West Warwick, Rhode Island, U.S.A.). B.P.560,448 of 4/11/1941:5/4/1944. Compounds suitable for rendering textile fibres water repelling have the general formula  $\text{RCOO} \cdot \text{CHR}' \cdot \text{N}(\text{tert.})\text{X}$ , where R stands for an alkyl radical containing not less than 10 C atoms, R' is H or an alkyl radical, X represents halogen or a weak carboxylic acid anion radical, and N(tert.) is pyridine, quinoline, triethanolamine or trimethylamine. Compounds in which X is halogen may be readily synthesized from aliphatic aldehydes, the acid halides of the higher fatty acids such as stearic, palmitic and lauric acids, and a tertiary amine. Compounds in which X is chlorine may also be prepared by reacting thionyl chloride with appropriate

acids and aldehydes and treating the products with a tertiary amine. Compounds in which X represents a weak carboxylic acid anion radical may be made by reacting together the higher fatty acid, thionyl chloride, a weak carboxylic acid and the aldehyde and mixing the resulting product with the tertiary amine. The products dissolve in water to form cloudy, strongly foaming solutions. One per cent. solutions are usually satisfactory for producing a permanent water repelling effect on textile fibres. Fibres or fabrics are immersed in a solution, passed between pressure rollers, dried at room or slightly higher temperature, and then baked in an oven at an elevated temperature. C.

**Azo Dyes: Production.** Society of Chemical Industry in Basle. B.P.560,451 of 3/4/1942:5/4/1944 (Conv. 3/4/1941 and 19/2/1942). Azo dyes are made by coupling in an alkaline medium a diazotised 2-amino-4-chloro-1-hydroxybenzene free from sulphonic acid groups and containing a nitro group as substituent in the 5- or 6-position with an azo dye of given general formula produced by the one-sided coupling of a tetrazotised benzidine with salicylic acid, or a substitution product thereof, and coupling the resulting diazo-azo compound with 2-amino-5-hydroxynaphthalene-7-sulphonic acid in an acid medium. The resulting dyes when after-coppered, give brown to violet-brown dyeings, fast to washing and light. They are suitable for dyeing and printing natural and regenerated cellulose fibres and animal fibres. C.

**Sulphonated Monoazo Dyes: Production.** Society of Chemical Industry in Basle. B.P.560,452 of 23/4/1942:5/4/1944 (Conv. 25/4/1941). Monosulphonated monoazo dyes, which have very good levelling properties and yield dyeings on wool that are fast to light and perspiration, are made by coupling the diazo compound of a sulphone of the general formula  $R_1SO_2R_2$ , in which  $R_1$  and  $R_2$  denote aromatic nuclei of the benzene series, one of which nuclei contains an amino group in meta-position to the  $SO_2$  group, in an acid medium with 2-amino-8-hydroxynaphthalene-6-sulphonic acid. C.

**Water-repellent Finishes: Production.** American Cyanamid Co. B.P.560,532 of 9/7/1942:7/4/1944 (Conv. 30/8/1941). A composition for finishing textiles comprises an aqueous emulsion or dispersion of an alcohol-reacted melamine-aldehyde condensation product, in the presence of a salt of an alkoxypropylamine containing at least 11 C atoms in the cation. The best results are obtained with melamine-formaldehyde condensation products containing from 2.5 and preferably about 4 moles of formaldehyde for each mole of melamine. The condensation products are preferably reacted with lower aliphatic alcohols such as methyl alcohol or butyl alcohol to the solvent-soluble stage, after which suitable amounts of other organic solvents may be added. A suitable alkoxypropylamine salt, preferably a di-(octadecoxypropyl)amine salt, is then dissolved at room temperature in the resin solution and water is slowly added with rapid, efficient stirring until an emulsion of the water-in-oil type having a particle size of  $1\mu$  or less is obtained. For application to fabrics this emulsion is further diluted with about 5 to 10 times its weight of water at 70-120° F. and the cloth is passed through the bath under conditions such that the amount of finish will range from 3 per cent. to 12 per cent. The cloth is then preferably dried at 240-250° F. after which the resin is cured for 4 min. at 285-310° F. or higher. The finished cloth has a soft, full handle and good water-repellency. The finish is stable upon storage and is resistant to laundering and dry cleaning. C.

**Polymeric Ester Coating Materials: Production.** E. I. Du Pont de Nemours & Co. and H. S. Rothrock. B.P.560,663 of 29/4/1942:14/4/1944. Polymers are obtained by heating in the presence of a metallic drier an ester of an unsaturated polycarboxylic acid and an aliphatic unsaturated monohydric alcohol in which alcohol the carbinol group is attached only to a saturated carbon atom. The polymerisation is carried out in thin films in the presence of the metallic drier whereby superior hard, flexible, light-coloured films are obtained. Alcohols useful in making the esters include allyl carbinol and China wood oil alcohol. The acids may be aliphatic, hydroaromatic or aromatic unsaturated polycarboxylic acids. Preferred metallic drier catalysts are the Co, Mn and Pb salts of naphthenic and linoleic acids. The polymeric materials prepared by this method are useful as vehicles for coating, impregnating or adhesive compositions. C.

**Photo-chemical Action Protective Colour Screen.** M. R. Coe (Washington, U.S.A.). B.P.560,714 of 21/4/1942:18/4/1944. A method of inhibiting deleterious or undesirable photo-chemical action on rubber, tobacco, foods, oils, fats, waxes, preparations containing vitamins and enzymes, and other commodities, comprises shielding them by means of a colour screen which is opaque to light having wave lengths between 6300 and 6700 Å. and below 4900 Å., but which will transmit substantially all other light. Screens in the form of protective shields, plates, caps, bags, formed containers or container linings may be used. The screen may be made of translucent or transparent material such as glass, glassine, synthetic resin, cellulosic material, etc., in which suitable dyes or colouring substances are incorporated. Malachite green, Monastral green, Fast green (A-5832) or chlorophyll pigment with the addition of a yellow dye or pigment such as "Azosol" fast yellow (ogga) may be used to produce the desired spectral absorption characteristics. C.

**Vat Dye Printing Preparations.** Durand & Huguenin A.-G. (Basle). B.P. 560,747 of 24/11/1941:19/4/1944 (Conv. 11/12/1940). Vat dye preparations for printing fabrics are made by dissolving in an aliphatic monohydric alcohol, polyhydric alcohol, ether thereof, aliphatic hydroxycarboxylic acid or ester thereof, or thiodiglycol, a cellulose derivative, an ester salt of a leuco vat dye and an oxidising agent and treating the solution with an organic acid, whereby the vat dye is re-formed in a finely divided state from the ester salt. An addition of urea to the solution is advantageous and the addition of a softening agent is advisable. By printing with such preparations and drying in the ordinary way, prints of very good yield, brightness and fastness to rubbing are obtained. C.

**Mordant Dyes: Chroming.** J. R. Geigy A.-G. (Basle). B.P.560,787 of 14/10/1942:20/4/1944 (Conv. 15/10/1941). A process for chroming *o*:*o*'-dihydroxyazo, *o*-hydroxy-*o*'-carboxyazo, or *o*-hydroxycarboxyl dyes, free from sulphonic acid groups, consists in treating such a dye in aqueous solution or suspension at raised temperature with a complex chromium compound of an aromatic *o*-hydroxycarboxylic acid and in doing so using at least one atom of chromium for each mordant grouping of the dye. Water-soluble chromium compounds of the dyes are obtained. The soluble chromium compounds of the *o*-hydroxycarboxy dyes produced in this way may be used for dyeing cellulose e.g. cotton or paper, and for dyeing silk and leather. The chromium compounds of the *o*:*o*'-dihydroxyazo and *o*-hydroxy-*o*'-carboxyazo dyes, free from sulphonic acid groups, draw uniformly, from a weak acid bath, on animal fibres and partially also on cotton. They are also suitable for dyeing leather. C.

**Anthraquinone Dyes: Production.** E. I. Du Pont de Nemours & Co., A. J. Wuertz and D. X. Klein. B.P.560,817 of 15/7/1942:21/4/1944. Anthraquinone dyes are made by condensing halogeno-, nitro-, hydroxy-, or amino-anthraquinones, if desired wholly or in part in the form of their leuco compounds, with *m*-aminobenzyl alcohol or a nuclear-substituted derivative thereof. The dyes are suitable for cellulose acetate fibres, being fast to gas fumes. C.

**Azo Dyes: Production.** Society of Chemical Industry in Basle. B.P.560,842 of 6/7/1942:24/4/1944 (Conv. 5/7/1941 and 11/5/1942). Azo dyes which are capable of development on the fibre are made by tetrazotising an azo dye of given general formula and coupling with two mols of resorcinol or meta-amino-phenol (or one mol of each). In an example, 4-aminobenzene-(1-azo-2')-5'-amino-1'-hydroxynaphthalene-3'-sulphonic acid is tetrazotised and coupled with resorcinol. The product dyes cotton violet-black. Olive-black tints, which are very fast to washing, are obtained by after-treatment on the fibre with 1-diazo-4-nitrobenzene. The developed dyeings can be discharged pure white under neutral or alkaline conditions. C.

**Monoazo Wool Dyes: Production.** W. F. Beech, M. Mendoza and Imperial Chemical Industries Ltd. B.P.560,892 of 18/9/1942:25/4/1944. Chromable monoazo wool dyes are manufactured by coupling diazotised *o*-amino-phenol or -naphthol monosulphonic acids, which may carry simple substituents, such as halogen and nitro, with a 1-diphenyl-3-(methyl or phenyl)-5-pyrazolone wherein the phenyl groups may carry as substituents halogen, alkyl or alkoxy, but are otherwise unsubstituted. The dyes are suitable for application by the

meta-chrome process and yield strong orange-brown to bluish-red dyeings of good fastness to washing, milling, potting and light. C.

**Anthraquinone Dyes: Production.** A. Lowe, A. C. Robson and Imperial Chemical Industries Ltd. B.P.560,988 of 9/10/1942:1/5/1944. Water-soluble dyes of the anthraquinone series are made by treating 4-*p*-benzeneazo-anilinoanthraquinones in which at least one of the 1, 5 and 8 positions of the anthraquinone nucleus is occupied by an acylamino group, the 1, 5 and 8 positions not so occupied being either free from substituents or occupied by a halogen atom, in which the 2 position of the anthraquinone nucleus is either free or is occupied by a halogen atom, an alkyl radical or a sulphonic acid group, and in which the aromatic nuclei of the *p*-benzeneazoanilino group may be unsubstituted or may bear as substituents in any position, provided that not more than one position ortho to the NH group is blocked, hydroxyl, alkoxy, amino, alkyl or nitro groups or halogen atoms, with sulphur trioxide or chloro-sulphonic acid, preferably in sulphuric acid as a solvent, and, if necessary, further treating with sulphonating agents. The dyes dye wool in deep brown shades of very good fastness to light and to washing. C.

**Chlorite and Persulphate Bleach Liquor: Application.** Mathieson Alkali Works (New York). B.P.560,995 of 27/10/1942:1/5/1944 (Conv. 26/9/1941). Cellulosic materials, including wood pulp, cotton linters, rayon, and woven fabrics made from cellulose fibres, can be bleached to an exceptional whiteness and without substantial degradation, by subjecting them to the action of an aqueous solution containing an alkali metal or alkaline earth metal chlorite and an alkali metal or alkaline earth metal persulphate at a pH of about 3-11. Application of this treatment to cellulosic material which has been partially bleached with one or more conventional bleaching agents is particularly advantageous. C.

**Chlorite and Aldehyde Bleach Liquor: Application.** Mathieson Alkali Works (New York). B.P.561,022 of 6/10/1942:2/5/1944 (Conv. 8/10/1941). Cellulosic materials can be bleached to an exceptional whiteness without substantial degradation, by subjecting them to the action of an aqueous solution containing an alkali metal or alkaline earth metal chlorite and an aldehyde at a pH of about 3-9. Specified aldehydes include formaldehyde, acetaldehyde, furfural, benzaldehyde, the 5- and 6-carbon atom aldose sugars and inverted sucrose. Phosphates are preferably used to control the pH of the bleaching solution. The method is applicable to the bleaching of wood pulp, cotton linters, rayon and cellulosic fabrics. A combined operation in which the cellulosic material is partially bleached with one or more conventional bleaching agents and the bleaching completed by treatment with a chlorite and an aldehyde is particularly advantageous. C.

**Metallized Azo Pigments: Production.** Imperial Chemical Industries Ltd. B.P.561,054 of 29/7/1942:3/5/1944 (Conv. 31/7/1941). Metallized azo pigments are made by coupling in aqueous medium a diazotised arylamine or heterocyclic amine which is devoid of hydroxy and of ether groups adjacent to the diazotised amino group, and devoid of sulphonic acid and carboxy groups, with a compound of the 4-hydroxy-2-pyridone series and metallising in an aqueous or aqueous-alcoholic medium by reaction with a water-soluble salt of a divalent metal having an atomic weight of between 50 and 66 in the proportion of one atomic equivalent of the metal to two molecular equivalents of the pyridone radical. The metal salt may be present during the coupling or added after coupling is complete. Suitable compounds of the 4-hydroxy-2-pyridone series comprise 4-hydroxy-2-pyridone which may carry substituents attached to the nitrogen atom which are phenyl, cyclohexyl or alkyl having 1 to 8 carbon atoms, and which may carry substituents in 5- and 6-positions which are alkyl having 1 or 2 carbons, halogen or nitro, or which taken together form with the 5- and 6-carbon atoms an isocyclic ring, which may be substituted by halogen, methyl, methoxy, ethoxy or nitro groups, or may be in the form of a benzo derivative. Products metallised with nickel, cobalt or copper show the best light fastness. C.

**Metallisable Direct Dyes: Production.** J. R. Geigy A.-G. (Basle). B.P. 561,117 of 5/11/1942:5/5/1944 (Conv. 6/11/1941). Metallisable direct dyes are obtained by condensing, in the presence of caustic alkali, an aminoazo dye

of given general formula with a triazole of the type produced by treating with oxidising agents monoazo dyes obtained from diazotised 4-nitro-4'-aminostilbene-2:2'-disulphonic acid by coupling with naphthyl amino derivatives coupling in *o*-position to the amino group. Specified aminoazo dyes include dyes produced by coupling diazotised 2-amino-1-hydroxybenzene-4-sulphonic acid with 2:5-dimethoxyaniline, and 1-hydroxy-2-diazo-4-nitrobenzene with *m*-anisidine. The products may be after-treated with oxidising and with metal-yielding agents. Alternatively, copper compounds of the aminoazo dyes may be used in the condensation. The copper complex compounds give brown, olive and orange shades on cellulose fibres. C.

**Pelts or Furs: Setting Hair.** S. Gottfried (to Pannonia (London) Ltd.). U.S.P.2,323,751 of 6/7/1943 (through *Chem. Abs.*, 1944, 38, 278). The hair is treated with formaldehyde vapour and, while some aldehyde remains on the hair, it is subjected to the simultaneous action of mechanical pressure and heat to cause setting. W.

**Peroxide Bleach Liquor: Stabilization.** E. I. Du Pont de Nemours & Co. U.S.P.2,333,916. A solution of a per-compound at pH 11.5 (or more alkaline), containing an alkali pyrophosphate, is stabilized by means of a magnesium salt. C.

**Polyamide Coating Composition: Application.** E. I. Du Pont de Nemours & Co. U.S.P.2,333,917. Fabric is given a base coating of a synthetic linear inter-polyamide and then coated with a reaction product of an organic poly-isocyanate with a linear poly-ester-amide in which 50-95 per cent. of the ester+amide groups are ester groups. C.

**Continuous Peroxide Bleach.** E. I. Du Pont de Nemours & Co. U.S.P.2,334,066. The claim is for a process in which the cloth is impregnated with an alkaline solution of a per-compound, rapidly heated to 200-212°F. by passage in contact with steam, and stored out of contact with the main body of the liquor or steam under such conditions that heat losses are reduced, but no further heat input occurs for at least 30 minutes. C.

**Cloth Coating Machine Doctor Rod.** Dow Chemical Co. U.S.P.2,334,102. Apparatus for coating flexible sheet material is fitted with a smooth rotatable doctor rod, not more than  $\frac{1}{8}$ -in. thick, supported rigidly, and heated. C.

**Alkyd Resin Finishing Emulsion.** American Cyanamid Co. U.S.P.2,334,107. An emulsion for imparting a full, crisp handle to textile fabrics contains 30-60 per cent. of an alkyd resin having an acid number not more than about 27.5, e.g. ethylene or propylene glycol phthalate. C.

**Sliver Dyeing Package: Winding.** Abbott Machine Co. U.S.P.2,334,165. Sliver is cross-wound on a frictionally-rotated perforated barrel, the pitch of traverse being progressively decreased to compensate for the increase of weight so that the tension in the sliver is equalized. C.

**Dye and Resin Emulsion: Padding.** Copeman Laboratories Co. U.S.P.2,334,199. Textiles are padded with an emulsion containing an organic solvent, a resin and a dye, and then dried, so that the discrete fibres are bonded by a film of coloured resinous substance. C.

**Dichloroethylene Co-polymer Coating Composition.** E. I. Du Pont de Nemours & Co. U.S.P.2,334,236. Cellulosic material is coated with a co-polymer of unsymmetrical dichloroethylene (40-80 per cent.) and at least one different polymerizable compound containing the group XC:CH<sub>2</sub>, X being a negative group devoid of unsaturated C—C bonds. C.

## 5—ANALYSIS, TESTING, GRADING AND DEFECTS

### (A)—FIBRES

**Coloured Cottons: Characteristics.** *Cotton (M/cr.)*, 1944, 50, No. 2406, p. 5. United States Department of Agriculture laboratories have been developing white, brown, and green lint cottons. Brown lint occurs in every known species the intensity of the colour ranging from a very faint cream as in Pima-Egyptian, to a very dark brown, as in Nankeen, an Upland cotton. Green pigmented cotton occurs only in one species, American Upland. Green-lint strains have the highest wax content of all cottons. The possibility of combining, through hybridization and subsequent selection, this wax content with the lint colour

and other desirable characteristics of the commercial white lint strains is of interest. The pigment affecting the colouration of several brown-like strains is found in the lumen or protoplasmic debris of the cell, and the colour does not develop until the boll opens. The green pigment occurs in the cell wall; it may be seen soon after the fibres begin to thicken and is apparent by 25 days after flowering. As the fibres develop, the colour is intensified until the boll opens, displaying the bright green pigmentation. On exposure to light, the colour gradually fades to a brownish green. It is doubtful if these cottons will ever be grown commercially to supply fibre for making cloth which would not have to be dyed. They are characterised by very low yields and very low lint percentages. The brown lints are very short and weak, and fabrics made from them are very mottled because of the variation in intensity of the pigments. The green-lint fibres are 100 per cent. immature. They have, however, been made into yarn that is as strong as the yarn ordinarily obtained from longer cottons. The instability of the green pigmentation would prevent the commercial use of green fibres as a means of obtaining natural coloured fabrics. C.

**Degraded Fibres: Electron Microscope Investigations.** E. Husemann and A. Carnap. *J. makromol. Chem.*, 1943, 1, 16-27 (through *Chem. Abstr.*, 1944, 38, 1107<sup>9</sup>). A preliminary report is given of the appearance under the electron microscope of cotton, beech pulp, various rayons, wool, silk and polyamide fibres which had been heated at 60° with 2N. hydrochloric acid or 0.5M. K bisulphate for times from 1 hour to 116 days. The oblong fragments appeared as fibrils; the finest of these were from the native cellulose and had a diameter of about 60 Å., whereas the fibres from the other materials were considerably thicker and showed less tendency to split into finer fibrils. C.

**Dyed Pulp Fibres: Dichroism.** P. R. Wiley. *Amer. Dyes. Rept.*, 1944, 33, 95-98, 110-116. The dichroism of dyed cellulose fibres is generally considered to be due to an orientated adsorption of dye particles possessing intrinsic dichroism on an orientated cellulose structure. A brief historical review of the phenomenon is given. A photo-electric instrument is described which has been designed for the measurement of the transmittances of dyed pulp fibres for light polarized at any desired angle with the fibre axis. The validity of choosing a relation between the transmittances obtained for the two cases where the plane of polarization is parallel and perpendicular to the fibre axis as a means of expressing the degree of dichroism of the fibre is demonstrated. The relation selected is the ratio of absorption coefficients for parallel and perpendicular polarization for a given wave length and depth of dyeing. Using the above mentioned instrument and relation, a study has been made of the factors affecting the dichroism of dyed pulp fibres and hence of the extent to which a dye is oriented on the fibres. The results show that the dichroism increased with decreasing amounts of lignin in the pulp. Short-fibred fractions of pulp exhibited less dichroism than long-fibred fractions. Treatment with chemical swelling agents decreased and beating increased the dichroism of the pulp. Dichroism increased with addition of salt to the dyebath and with increase in the concentration of the dye in the bath. Variation of the temperature of the dyebath appeared to have no appreciable effect. An attempt is made to explain these effects and show their significance. C.

**Fibres: Interference Colours in the Polarization Microscope.** A. Herzog. *Kleppig's Textil-Z.*, 1943, 46, 171-177 (through *Chem. Zentr.*, 1943, i, 2654 and *Chem. Abstr.*, 1944, 38, 1118<sup>9</sup>). The most important interference colours of several natural fibres, interference colours in daylight, and addition and subtraction colours obtained by the use of Gypsum Plate Red I are discussed and a diagnostic scheme is developed. The dichroism of many fibres after dyeing or incorporation of colloidal metals or non-metals is discussed. C.

**Cellulose Fibres: Heat of Water Sorption.** K. Lauer, R. Döderlein, C. Jäckel and O. Wilde. *J. makromol. Chem.*, 1943, 1, 76-96 (through *Chem. Abstr.*, 1944, 38, 1354<sup>9</sup>). The heat of adsorption was determined for a number of pulps (including spruce, pine, cereal straws and other plants), viscose rayon and staple fibres from various woods, straws, etc., and ramie, cotton and filter paper. Ramie, cotton, and filter paper (and certain pulps) gave an average value of 1.69 ( $\pm 5$  per cent.) kg.-cal./mole  $C_6H_{10}O_5$ , pulps gave a value of 2.11 ( $\pm 10$  per cent.), and viscose rayon and staple fibres gave 3.41 ( $\pm 8$  per cent.).

After extracting the pulps with aqueous caustic soda (removal of hemicelluloses), the heats of adsorption were the same as for ramie, cotton and filter paper. The extracted hemicelluloses gave a value of 4.8 kg.-cal./mole  $C_6H_{10}O_5$ . The heat of adsorption ("heat of solvation") for regenerated cellulose was thus twice that of native cellulose. Calculated for 1 mole of water, the heat of adsorption was 3.40 kg.-cal. for both types of fibres. This value is very nearly that of the heat of hydration (per mole of water) liberated on the formation of solid sugar hydrates from crystalline  $\beta$ -sugars and liquid water and that of the heat of mixing of ethyl alcohol with water. This agreement is in favour of hydrate formation between cellulose and water. This is discussed in terms of the intermicellar distances. The heat of adsorption of mercerised celluloses increased with the time of mercerisation with 20 per cent. caustic soda at 20° (the degree of polymerisation was practically unchanged); this increase is explained by an increase in the amorphous portion. Degradation with acids or treatment in an oscillating mill did not change the heats of adsorption of rayon, ramie and wood pulps; likewise, heating in glycol caused no change. In spite of their greater internal surface, the heat of adsorption of isotropic fibres (i.e. showing no elongation) was not higher than that for regenerated fibres (2.38-2.66 as compared with 3.41); fibres prepared by spinning into 60-65 per cent. sulphuric acid have values of 3.08 and 3.40.

**Cellulose Fibres: Wet Strength and Elongation.** (1) K. Lauer. (2) W. Mansch and K. Lauer. *J. makromol. Chem.*, 1943, 1, 97-105, 106-112 (through *Chem. Abstr.*, 1944, 38, 1355<sup>4</sup>). (1) Differences in the wet strength of natural and regenerated cellulose fibres may be a result of chain length, crystal lattice arrangement or fibrous structure (e.g. spiral and vertical orientation of the fibre elements). The relative wet strength of American and Egyptian cottons and ramie which had been mercerised with and without stretching were determined to 100.25 per cent. of the dry strength (i.e. values close to those for unmercerised fibres); also for cotton degraded with aqueous hydrochloric acid for 6 hours at 55° and that mercerised prior to degradation. The fact that the relative wet strength of the last two was nearly the same (about 100 per cent.) indicates that the value is not influenced by the crystal lattice arrangement or the chain length. The wet strengths for viscose rayon fibres before and after reversion to the native form (heating with ethylene glycol and tetrahydrofurfuryl alcohol) were 52-7.5 per cent.; this indicates that polymorphism is not responsible for the wet strength. The absolute breaking length of rayon fibres increased with increasing degree of stretching, but the relative wet strength remained practically unchanged. No relation could be established between the degree of orientation and the magnitude of the relative wet strength. It is concluded that it is impossible to increase the relative wet strength of regenerated cellulose fibres to any extent merely by stretching. For regenerated fibres the breaking length did not decrease until the moisture content was above the adsorption limit, whereas for cotton the value increased with increasing moisture content within the adsorption range and then became constant. (2) A theoretical treatment of investigation of the elongation process by means of tension-elongation curves.

**Cotton Fibre: Variation of Length in Bulk and on a Single Seed.** R. L. N. Iyengar. *Indian Textile J.*, 1944, 54, 197-199. The author took half a pound of seed cotton from a bulk sample, selected by a suitable sampling technique ten seeds, passed each seed through a hand gin and weighed each yield of lint, and then ginned the remainder of the half-pound. The lint from each individual seed and two tufts of lint from the main supply were then examined by means of the stapling apparatus of Ahmad and Nanjundayya with the attachment for obtaining the fibre length distribution (1938). The test was applied to Sind Sudhar, Jayawant, Surat 1027 A.L.F., and Punjab-American 4F cottons. A table records the weight of lint put through the stapling test, the mean fibre length, the standard deviation and the coefficient of variation (C.V.). The values of C.V. are all in the neighbourhood of 20 per cent. and the values for individual seeds are not really lower than those for the bulk. This suggests that because the variation on a single seed is so large the relatively smaller variations between seeds, bolls, plants, etc., that are added in the bulk samples are without much influence on the total variation.

**Cotton and Rayon Fibres: X-Ray Diagrams.** I. Fankuchen and H. Mark. *Record Chem. Progress*, 1943, 4, 54-57 (through *Chem. Abstr.*, 1944, 38, 1357<sup>3</sup>). New experiments are reported on monochromatic diagrams of the cellulose fibre, and on X-ray diagrams of single fibres in search of information concerning the nature of viscose, acetate, nylon, Saran and other artificial filaments. C.

**Electron Microscope: Construction and Application.** H. Hunter. *Textile Weekly*, 1944, 33, 782-8. A popular account of the theory of the use of electron beams for "seeing" objects too small for the optical microscope, a brief description of the electron microscope (Radio Corporation of America), and suggestions for its use in textile research. C.

**Linear Polyamide Fibres: Structures and Properties; Effect of N-methylation.** W. O. Baker and C. S. Fuller. *Ann. N.Y. Acad. Sci.*, 1943, 44, 329-349 (through *Phys. Abstr.*, 1944, 47 A, 42-43). A series of nine N-methylated polyamides, with methyl substitution varying in polydecamethylene sebacamide from 0 to 55 mol. per cent., was studied. Young's modulus, moisture sorption and relative solubility were chosen as properties representing the gross solids, whilst the corresponding fine structure was studied by X-ray diffraction from oriented and unoriented sections. The elastic modulus and hardness decrease with increasing N-methylation, relative solubility increases and moisture sorption increases. The interchain spacings are not changed by the methyl substitution, but at higher amounts of substitution one of the principal spacings (3.76 Å.) becomes diffuse. The chains appear retracted by partial folding along the fibre axis. C.

**The Wyoming System for Scoring Corriedale Sheep.** F. S. Hultz. *University of Wyoming: Agric. Exper. Sta., Bull.* No. 258, 1943. A scoring system used in connection with the experimental breeding of Corriedales consists of the use of graphic charts with line symbols for describing the conformation of the sheep, and of standard photographs in three poses against a checkered background. The results of the body analyses are discussed. The wool analyses are based on a fleece score which places 80 per cent. of emphasis on the clean wool produced, 10 per cent. on the variability of fibre diameter and 10 per cent. on type of crimp. The fleece score for each sheep is computed from the formula:

$$\text{fleece score} = 8 \frac{(\text{wool weight value} + \text{variability value} + \text{crimp value})}{10}$$

A set of standards of crimp type is presented, the designations suggested being bold, distinct, intermediate and dim. W.

**Proposed Methods of Test for Estimating the Clean Wool Content in Wool in the Grease.** Amer. Soc. for Testing Materials, Committee D-13. *A.S.T.M. Standards on Textile Materials*, 1943, 385-389. The following methods are proposed for determining the clean wool contents of different types of raw wool: (1) scouring, carding and combing, (2) scouring and determining vegetable matter on a laboratory scale, (3) scouring and carbonising (all wool found in wastes to be included), (4) scouring, drying and testing, then carbonising and adding average correction for wool lost. The method is also applicable to mohair, alpaca, camel hair, cashmere and vicuna. W.

**Standard Method of Test for Hard Scoured Wool in Wool in the Grease. D 584, 1943.** Amer. Soc. for Testing Materials, Committee D-13. *A.S.T.M. Standards on Textile Materials*, 1943, 281-284. Hard scoured wool shall be wool having a regain of 13.6 per cent. (equivalent to 12 per cent. moisture content), a combined ether and alcohol extractable matter content of 1.5 per cent. and an ash content of 0.5 per cent. Laboratory test methods are given for scouring and drying samples of opened wool, for determining ether and alcohol extractable matter and ash, and for calculating the percentage of hard scoured wool as defined above. W.

#### (B)—YARNS

**Strength Testing Machine.** L. Gillemot. *Technika* (Budapest), 1942, 23, 385-393 (through *Chem. Zentr.*, 1943, ii, 1162-1163 and *Chem. Abstr.*, 1944, 38, 1110<sup>9</sup>). The theoretical basis and a description are given of a tensile strength testing machine for paper, leather and textile investigations which has a range of 200-400 and 40-1000 kg. The error is 0.1-0.2 per cent. C.

**Cambridge Textile Extensometer.** Cambridge Instrument Co. *Textile Manufacturer*, 1944, 70, 171, 179. An illustrated description is given of an instrument for making the load/extension diagram of fibres or yarns, at constant rate of loading or constant rate of extension. The specimen and a spring are simultaneously extended by independent means, a constant speed motor being normally used for the spring and a second motor for the specimen. This motor is switched on and off by a sensitive device that keeps the tensions equal in the specimen and spring. C.

**Textile Testing Machines: Reduction of Vibration.** R. W. Vose. *Textile Research*, 1944, 14, 76-79. A critical study of a Scott pendulum type tensile tester, a Saco-Lowell sliver tester, and a Belger roving tester revealed the outstanding defects in all the machines to be considerable inertia and a tendency towards vibration, which severely limited the operating speed. To improve the sliver tester, the weights were hung on springs, the lever system was reconstructed from light metals and with very light sections at all points, and the tracing pen was also lightened. The speed of the machine was increased to approximately seven times its original value by providing new gears, and a small rubber bushing was inserted in one of the links of the recording mechanism to eliminate a slight vibration from the gears. Changes in the chart drive made it possible to condense the record from an entire can of sliver into a chart not over a yard long. In the roving tester a spring was substituted for the gravity pendulum with changeable weights and it was found possible to increase the speed by about five or six times. An entire 1.4 lb. bobbin of 1.65-hank roving could be tested in about 20 min. Changes in the chart speed were made to condense the record and rolls of adding machine paper were substituted for the original printed chart. Cyclic errors of considerable magnitude between the actual load and the indication of the machine were observed with the pendulum-type tensile tester. It was also noticed that the inertia of the pendulum comes into play after the fracture of the specimen so that the machine overshoots the actual load at fracture. This machine is unsatisfactory for use on new materials of high elasticity or others with unusual properties. C.

**"Grex" Yarn Counts System.** A. G. Scroggie. *Rayon Textile Monthly*, 1944, 25, 17-19, 69-71, 121-122; *Textile World*, 1944, 94, No. 1, 84-85; *Cotton (U.S.)*, 1944, 108, No. 1, 71-74; No. 2, 99-101; *Textile Manufacturer*, 1944, 70, 180-183. W. H. Slater. *Textile Weekly*, 1944, 33, 632-6. The proposed "grams per 10,000 metres" system of yarn counts is explained and arguments are advanced for its general adoption. C.

**Rayon Yarn: Testing and Quality Control.** C. W. Bendigo. *Textile World*, 1944, 94, No. 3, 86-87. A brief review of routine tests for quality control in rayon thread production with special reference to (1) twist testing, (2) stroboscopic check of spindle speed, (3) load/extension tests on the inclined plane machine, (4) uptake of soaking solution, and (5) density of package. C.

**Cuprammonium Dispersions of Cotton and Rayon Fabric: Flow Characteristics.** Viola C. Jelinck. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 172-178. The flow characteristics of cotton and regenerated cellulose fabrics dispersed in cuprammonium solution were determined by means of flow/pressure and fluidity/velocity gradient graphs. Under the experimental conditions recommended by the American Society for Testing Materials, 0.5 per cent. cotton-cuprammonium dispersions with fluidity values ( $F_c$  corrected for kinetic energy) greater than 19 rhes and 2 per cent. regenerated cellulose dispersions are simple liquids; 0.5 per cent. cotton-cuprammonium dispersions with  $F_c$  values less than 17 rhes are complex liquids rather than plastic materials, since they do not exhibit a real yield value. The equation  $F_0 = C'/t$  may be used for the calculation of fluidity values less than 7 rhes, since the kinetic energy correction for these values is negligible. Either the Poiseuille equation or the equation  $F_c = C'/(t - K/t)$ , more frequently used in calculating the fluidity of cellulose dispersions, is suitable for calculating fluidity values greater than 7 rhes. The velocity gradient adjustment is applicable to the complex cotton-cuprammonium dispersions with  $F_c$  values less than 10 rhes. The equation  $F_0 = q/C(P - p)$ , intended for plastic materials, should not be used for calculating the fluidities of cellulose fabrics since they form either simple or complex rather than plastic dispersions, and they often require the kinetic energy correction. ( $F_0$  is Bing-

ham's mobility value which is not corrected for kinetic energy,  $q$  is the rate of flow in millilitres per second,  $C$  is the instrument constant,  $P$  the hydrostatic pressure and  $p$  the yield value,  $C' = C/d$  where  $d$  is the density of the cuprammonium solvent,  $t$  is time of flow in seconds, and  $K$  is the kinetic energy correction constant). Either the burette consistometer or the viscometer may be used for regenerated cellulose dispersions or cotton dispersions with  $F_c$  values greater than 10 rhes. The burette type of capillary instrument has an advantage over the single-volume viscometer type for the determination of the fluidity of complex cotton-cuprammonium dispersions with  $F_c$  values less than 10 rhes, since the velocity gradient adjustment is readily obtained with the burette consistometer in one discharge. C.

#### (C)—FABRICS

**Aeroplane Fabric Punch Tester.** *Engineer*, 1944, 177, 347. A practical method of testing aeroplane fabric for strength has been made possible by the development of an automatic mechanical tester by the United States Civil Aeronautics Administration. The device operates similarly to a spring centre punch. When the disc-like pad is placed against the fabric and the handle pressed down, a centre plunger is driven through the pad and against the fabric with a known force. The tester can be used on a fabric anywhere about an aeroplane, eliminating the need of cutting out pieces. The internal spring is adjusted to various grades of fabric. The plunger makes a slight dimple in the finish of fresh, live fabric, and the mark soon disappears. Tendered fabric, even though stretched taut by a fresh coat of dope, gives way before the plunger, which either makes a clean hole or produces permanent cracks in the finish. C.

**"Crown" Tested Rayon Fabrics: Quality Control.** A. R. Wachter. *Amer. Dyes. Rept.*, 1944, 33, 100-105. The Quality Control Plan introduced by the American Viscose Corporation in 1930 and applied first to knitted rayon underwear and then to woven fabrics is briefly discussed and an account is given of the "Crown" Tested Plan introduced by this company in 1942. Under this plan, fabrics by licensees of the American Viscose Corporation, containing the company's "Crown" Rayon may be submitted for fabric stability tests, including fabric strength, seam slippage, dimensional restorability, colour fastness, permanence of finish and other qualities. Minimum Test Requirements have been established for rayon fabrics for men's wear, women's wear and home furnishings, special attention being paid to the particular use to which the fabric will be put. Samples of every colour of every dye lot are tested. Fabrics which pass the tests become eligible to carry identification as "Crown" Tested, which will be indicated to the consumer by the presence of a "Crown" Tested tag or label. Every effort has been made to make the "Crown" Tested tags or labels truly informative and helpful to retailers and customers. Each Minimum Requirement specifies the tests which the fabric must meet to carry identification as "Crown" Tested. The nature of some of these tests is indicated. C.

**Dyed and Printed Cotton Fabrics: Fastness to Washing.** G. A. Moran. *Amer. Dyes. Rept.*, 1944, 33, 105-106. The effects of friction or rubbing on dyed or printed cotton materials and differences in the behaviour of vat and naphthol dyes and pigments in standard tests for fastness to washing and on laundering are discussed. A friction, rub or abrasion test is suggested, which will indicate the effects of subjecting the material to energetic friction or rubbing action with soap and water. A modified crockmeter is used for this test. The sample, wet out in standard soap solution, is so attached to the moving arm of the crockmeter that it will rub upon itself as many strokes as found suitable. An appreciable removal of colour will occur with "loose" colours. C.

**Fabrics: Strength Testing.** *Textile World*, 1944, 94, No. 2, 146. The writer suggests the need for experiment on and standardisation of the method of tightening the grips in cloth strength tests. Stress/strain curves are reproduced for specimens with (1) the grips tightened at the outset, (2) the grips tightened on reaching the critical point (a load of 400 lb.), (3) the grips gradually tightened during the test. No. 1 gave a smooth curve, (2) gave a more erratic curve until the grips were tightened, and a higher break, and (3) was still more erratic and gave the highest break. Method (2) is preferred by the writer. C.

**Rayon Stockings: Wearing Qualities.** Hazel M. Fletcher. *Rayon Textile Monthly*, 1944, 25, 86-87, 136-138. A series of tables record the data collected in a study of the wearing qualities of viscose, cuprammonium and acetate rayon stockings, worn by 15 people. Table I gives the type of reinforcement, price, shrinkage in the wash, yarn count and filament denier, and knitted construction; II-V, the bursting pressure at various parts, for new and worn stockings, with the analyses of variance; and VI-VIII, the hours of wear, number of launderings, and fading indexes, with analyses of variance. A set of load/extension diagrams of the yarns is also provided. The acetate rayon hose kept their shape and colour and fitted better than the others but wore into holes more readily. The three types were alike in bursting strength when new, but the viscose stockings wore on an average for 330.6 hours, the cuprammonium for 311.1 hours, and the acetate for 194.2 hours. C.

**Sized Cotton Cloth: Size Content Determination.** *Indian Textile J.*, 1944, 54, 192. Details are given of two methods for the determination of size content under the Indian Starch Control Order, 1943, with a list of nine laboratories authorised to perform the analysis. In the first method, size is removed by boiling the specimen in soap and soda. The second method consists of extraction with carbon tetrachloride followed by digestion with diastase. C.

**Proposed Method for the Quantitative Analysis of Textiles Composed of Wool and Lanital.** Amer. Soc. for Testing Materials, Committee D-13. *A.S.T.M. Standards on Textile Materials*, 1943, 383-384. A proposed flotation method is described for preparing the test specimen of yarn and the separating liquid, for making the actual separation and for calculating the lanital and wool contents of the cloth. W.

#### (D)—OTHER MATERIALS

**Elastensometer.** G. D. Kish. *Rubber Age*, 1943, 53, 131 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1943, 245). In the Elastensometer, an instrument for testing the elasticity of rubbers at low temperatures, the specimen, in the form of a simple beam, is supported over anvils and centrally loaded. The force required to produce a given constant deflection is transmitted through a spring and indicated on a scale. The base of the instrument is immersed in a cup of alcohol and the temperature is lowered by the addition of "dry ice." Results are reported in the form of temperature-load curves. Curves are shown for a typical safe low temperature material and a material whose critical temperature is above 0° F. The modulus of elasticity is obtained by the use of the conventional beam deflection formula. A diagrammatic illustration is given of the changing values of the modulus of elasticity of rubber-like material with decreasing temperature. Since the modulus of elasticity in bending tends to increase as the temperature is lowered, the limiting critical temperature as obtained with the Elastensometer may be defined as that temperature where the normal value for the modulus increases to the maximum value permitted for the application. Critical values are tabulated for a typical material. C.

**Elastomers: Tensiometer Stiffness Test.** B. K. Green, R. G. Chollar and G. J. Wilson. *Rubber Age*, 1943, 53, 319 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1943, 245 and B1.2: 145). Details are given of a tensiometer stiffness test for elastomers at low temperatures in which a Cenco du Nouy Precision Tensiometer, No. 10,402, is used. Young's modulus can be calculated from the tensiometer readings. The application of the test to Hycar OR samples is reported. Temperature/stiffness curves and data showing the variation of stiffness with thickness are presented. C.

**Plastic Sheets and Films: Gas Transmission.** H. R. Todd. *Paper Trade J.*, 1944, 118, TAPPI, 84-87. A simple volumetric apparatus for measuring the transmission of gases through sheets and films is described. The sheet separates a chamber of volume about 10 c.c. from one of about 500 c.c. The larger chamber is evacuated, whilst the smaller chamber is maintained at atmospheric pressure. The consequent movement of gas through the sheet, results in the movement of a column of liquid in a horizontal capillary tube to displace the gas transmitted from the small chamber. The volume of gas transmitted is thus measured directly. The sensitivity of the apparatus is approximately 0.019 c.c. per 100 sq. in. per 24 hours for a 24-hour period. Tests with ethyl-

temperature sometimes have very low brittle-point temperatures. The latter are therefore inadequate for use as indices of low-temperature serviceability. It is pointed out that although natural rubber is basically more cold resistant than some of the synthetic elastomers it is possible to compound synthetic elastomer stocks having better low-temperature properties than natural rubber stocks. C.

**Cellulose Bacteria: Activity.** W. H. Fuller and A. G. Norman. *J. Bacteriology*, 1943, 46, 273-289, 291-297 (through *Chem. Abstr.*, 1944, 38, 2017). Five new species of aerobic cellulose-decomposing organisms are described: *Pseudomonas ephemerozyanea*, *P. lasia*, *P. erythra*, *Achromobacter picrum* and *Bacillus aporrhoeus*. With the exception of *P. erythra* all are capable of growing well on many carbohydrates. *A. picrum* alone produces acid from cellulose and sugars. The more active of the organisms used about one-third of the filter paper supplied in 14 days. Cornstalk cellulose was far more extensively used by all of the organisms in an equal time. The presence of xylan in the cellulosan component of the cornstalk cellulose exerted a favourable influence on decomposition. About 75 per cent. of the xylan was more readily available than the remaining fourth. Cornstalk cellulose with the major part of the xylan removed resembled filter paper in availability. There is some evidence that a portion of the xylan may be present in imperfect cellulose chains. A series of preparations with decreasing lignin content was obtained from jute fibre by treatments with monoethanolamine. The extent of cellulose decomposition produced by the vigorous organisms, *Ps. ephemerozyanea* and *Sporocytophaga myxococoides*, increased as the lignin content decreased. Less vigorous organisms were little affected by the lignin content of the substrate. Both used the xylan component of the cellulose disproportionately. Both lignin and cellulose in the cell wall form interpenetrating systems; the effects of lignin in reducing the availability of cellulose are probably physical. C.

**Termite Protozoa: Digestion of Cellulose.** R. E. Hungate. *Ann. Entomol. Soc. America*, 1943, 36, 730-739 (through *Chem. Abstr.*, 1944, 38, 794<sup>9</sup>). Cellulose-digesting protozoa (the hypermastigote flagellates *Trichonympha colaris*, *T. campanula*, *T. sphaerica* and the polymastigote flagellate *Trichomonas termopsidis*) were removed from the alimentary tracts of termites (*Zoötermopsis nevadensis*, *Z. angusticollis*), suspended in an inorganic salt solution and allowed to act on powdered cellulose for periods up to 108 hours at 25.5°. The digestion products, which were recovered to 70-75 per cent. of the initial cellulose, consisted of carbon dioxide, hydrogen and acids, principally acetic acid (85 per cent. of total acid). No glucose was demonstrated as a product of cellulose digestion by the protozoa. Apparently, the principal carbonaceous materials used by *Zoötermopsis* are fermentation products produced by protozoa from the glucose which they obtain by cellulose digestion. Gas and acid (acetic acid, etc.) were identified as products of cellulose digestion by protozoa taken from the digestive tracts of another termite (*Reticulitermes flavipes*). Probably an anaerobic fermentation process is characteristic of most of the wood-digesting protozoa found in termites. Tests showed that acetic acid and probably also the non-volatile acids produced by the protozoa are absorbed from the mid-intestine of the termites. These acids are oxidised by the termites to obtain energy; carbon, carbon dioxide and hydrogen are eliminated. C.

**Proteolytic Enzymes: Activity Measurement; Gelatin Viscosity Reduction Method.** F. G. Lennox. *J. Council Sci. Ind. Res. (Australia)*, 1943, 16, 155-166 (through *Chem. Abstr.*, 1944, 38, 758<sup>9</sup>). The gelatinase activities of trypsin, papain, euphorbain and a mould protease were measured by means of the digestion flask viscometer. The time for a given change in viscosity bears no constant relation of concentration over a wide range of enzyme concentrations. Although the relation between viscosity after 10 min. at 40° and enzyme concentration always approximates to a hyperbolic form, the shapes of the curves for different enzymes and for different samples of the same enzyme diverge appreciably at high concentrations. Thus the activity cannot be expressed in terms of equivalent enzyme concentration by reference to a simple equation or calibration curve, and it is reported as reduction in viscosity of the enzyme-gelatin mixture after 10 min. at 40°, expressed as a fraction of the initial viscosity. Determination of the amino and carboxyl groups in

enzyme-gelatin mixtures shows that chemical splitting can be detected within 1-2 min. of adding the enzyme. After 8 min. at 40° certain highly active enzyme solutions have reduced the viscosity almost to a minimum value, and at this point approximately three peptide bonds are split per 10,000 g. of gelatin. If a molecular weight of 35,000 is assumed for gelatin, the average molecular weight of the resultant polypeptides would be approximately 2,800, which corresponds to chains of about 28 amino acid residues. C.

**Cellulose: Heterogeneous Degradation.** O. Eisenhut and E. Schwartz. *Die Chemie*, 1942, 55, 380-387 (through *Chem. Abstr.*, 1944, 38, 249'). Measurements of the changes in the degree of polymerisation show that the heterogeneous hydrolytic degradation does not proceed according to a zero-order reaction, as a slowing down with time occurs. The initial velocity of hydrolysis of various fibre types in ascending order is: native untreated fibre, native mercerised fibre and regenerated cellulose fibre. For all regenerated cellulose fibres the  $k$ -values of the zero-order reaction equation became equal after relatively short time of hydrolysis. Even with prolonged periods of hydrolysis, the  $k$ -values of the untreated cotton remained appreciably lower and those of mercerised cotton definitely lower than the values for the fibres from regenerated cellulose. The velocity of the hydrolytic degradation as a function of temperature and concentration was determined. The effect of caustic soda pretreatment upon the velocity of hydrolytic degradation and the solubility at various alkali concentrations was observed. The behaviour of sulphite pulp was also observed and an explanation presented for the initial deviation compared with the behaviour of cotton. Observations of the changes of the  $k$ -values and the X-ray structures of crude and alkali-treated cotton fibres are discussed. The slowing down of the degradation reaction in the course of hydrolysis is explained on the basis of localised attack areas where the acid attack leads to the rapid formation of very short cellulose chains which then greatly limit the further acid attack. Intermittent alkali treatments remove these chains and permit renewed acid attack. The relationship between breaking strength and degree of degradation was investigated; the decrease of the breaking strength is proportional to the time of exposure to the degrading substances and is independent of the alkali pretreatment of the fibre. The decrease of the degree of polymerisation, however, is accelerated by alkali pretreatment. The relationship between degradation velocity and alkali solubility of hydrolytically as well as alkali degraded cotton fibre was determined. C.

**Cellulose Molecules: Form and Mobility.** P. H. Hermans, J. de Booy and C. J. Maan. *Kolloid Z.*, 1943, 102, 169-180 (through *Chem. Abstr.*, 1944, 38, 248'). A new model of the cellulose molecule is developed on stereochemical considerations with the aid of known atomic distances, valence angles and effective radii of atoms. A space-angled position of the chain is required and rings of adjacent glucose groups cannot be quite parallel. The polarity of the chains must alternate and the chains in adjacent layers must be moved along the fibre axis by 3-4 Å. in relationship to each other. Rotation about the O bridge is assumed and there is a possibility of transition from the "chair" to the "trough" form. C.

**Methyl Linoleate: Chromatographic Purification.** C. E. Swift, W. G. Rose and G. S. Jamieson. *Oil & Soap*, 1943, 20, 249-250 (through *Chem. Abstr.*, 1944, 38, 655'). A column of alumina for chromatographic adsorption is prepared by alternately pouring alumina and light petroleum (36-60°) in small portions into a chromatograph tube (400 g. alumina adjusted to activity of IV in a tube 1½ in. diameter) with a glass rod for stirring. A portion, 4 g. methyl esters of cottonseed oil in 150 ml. of petroleum ether, is introduced and the chromatogram developed with 1400 ml. of light petroleum. By this procedure a fraction of iodine number 74.6 was obtained consisting of a mixture of methyl esters. The methyl linoleate was eluted by rapidly forcing 2.5 l. more of light petroleum through with pressure. From a total of 16 g. of methyl esters, iodine number 108, 5.2 g. of methyl linoleate having an iodine number of 159.5 were obtained. After further purification, this had the following constants: iodine number 170.4, thiocyanogen number 87.3,  $n_D^{25}$  1.4594. The product was 97.7 per cent. pure. C.

**Polyhydric Alcohol Fatty Acid Esters: Preparation, Properties and Uses.** H. A. Goldsmith. *Chemical Reviews*, 1943, 33, 257-349. The methods of preparation, physical and chemical properties, and industrial applications of the higher fatty acid esters of polyhydric alcohols and of polyhydroxy ethers are reviewed. The bibliography has 572 entries. C.

**Proteins: Reaction with Formaldehyde.** R. L. Wormell and M. A. G. Kaye. *Nature*, 1944, 153, 525. Animal and plant caseins can be deamidated by treatment with a solution of 1 per cent. caustic soda for 40 hours at 45° C. The desamido-casein, when hardened with formaldehyde under neutral conditions, combines with the same amount of formaldehyde as does the untreated casein. In the presence of salts, acids and formaldehyde, the neutral hardened deamidated material combines with no additional formaldehyde, whereas the untreated neutral hardened casein may increase its formaldehyde content by about 100 per cent. Partial deamination is also possible without the removal of amide nitrogen. The partially deaminated product combines with a reduced quantity of formaldehyde under neutral conditions. In contrast to this, the same partially deaminated product combines with a normal quantity of additional formaldehyde when treated with formaldehyde, salt and acid. When zein is hardened in a neutral solution it combines with only 0.4 per cent. of formaldehyde, but in the presence of salt and acid, the combined formaldehyde increases to 4.1 per cent. These figures are in keeping with the low amino and high amide contents of zein. The conclusion is drawn that, at or near the isoelectric point of the protein, formaldehyde combines with the amino groups mainly derived from lysine residues whereas under more acid conditions it combines with the amide groups attached to residues of glutamic and related acids. C.

**Osmotic Balance.** I. Jullander and T. Svedberg. *Nature*, 1944, 153, 523-524. An osmometer in which the liquid passing through the membrane is weighed can be used for osmotic pressures from a few cm. of water pressure to some hundredths of a cm. In an undamped analytical balance one of the scales is removed, and on the floor of the balance case is fixed a stand with an adjustable platform carrying a glass cylinder filled with solvent. The osmotic cell is constructed of aluminium and glass, the necessary cementings being made with litharge/glycerin. The lower part of the cell is conical with a basal diameter of 5 cm. At the apex is fixed a glass tube a few cm. long and 0.9 cm. inner diameter. The upper part of the glass tube has an aluminium collar, carrying a wire so that the cell can be hung on the balance arm. A semi-permeable membrane is attached to the base of the conical recipient by means of a threaded ring and a perforated membrane-support. The membrane itself acts as packing material against leakage. The osmotic cell and part of the glass tube are filled with solution and suspended on the balance in such a way that the cell dips into the solvent in the glass cylinder. By means of the adjustable platform the difference in level between the solution in the cell and the solvent in the glass cylinder can be varied. The balance is adjusted to neutral equilibrium. When the weight of the cell increases, the cell sinks until the buoyancy compensates the increased weight. Because of the minuteness of the displacements, the reading of the balance is magnified by means of a doubly reflected beam of light. Arrangements are provided for reducing evaporation losses and for eliminating electrostatic effects. The use of this device for measurements on nitrocellulose in butyl acetate is described. For a nitrocellulose made from American linters and having a nitrogen content of 12.28 per cent., the molecular weight (number-average) corresponding to the osmotic data is 148,000. C.

**Indian Green Earth: Base-exchanging Properties.** N. R. Damle, R. B. Forster and K. G. Kudva. *J. Indian Chem. Soc., Ind. Ed.*, 1943, 6, 30-39 (through *Brit. Chem. Physiol. Abstr.*, 1944, B II, 9). Green earth (Caledon earth:  $\text{SiO}_2$  66.1,  $\text{Fe}_2\text{O}_3$  6.3,  $\text{Al}_2\text{O}_3$  15.9 per cent.) adsorbs the cations of basic dyes and organic bases (aniline and *p*-phenylenediamine) irreversibly in proportion to their equivalent weight, all sorption curves being similar and not obeying Freundlich's law. The degree of sorption is decreased by pre-treatment of green earth with acids, but is increased by treatment with calcium, zinc or sodium chloride or sodium hydroxide, and is independent of the pH of the sorbate. Acid dyes and lakes are not sorbed. Ignition of green earth at 400° reduces, and at 800° abolishes, its sorptive power. Replacement of calcium by sodium

ions in green earth occurs on treatment with excess of sodium chloride. With fuller's earth, the degree of sorption is increased on treatment with acids. C.

**Hydrogen Bond: Occurrence.** L. Hunter. *Chemistry and Industry*, 1944, 155-157. A discussion of the nature of the hydrogen bond and essentials for its operation, the prevalence of the hydrogen bond in common substances, the influence of the hydrogen bond on the physical behaviour of water, hydrogen-bond association and tautomerism, hydrogen bonds involving atoms of fluorine, oxygen, nitrogen and sulphur, and evidence pointing to hydrogen bonds involving carbon. C.

**Bauxite: Use as Drying Adsorbent.** W. A. La Lande, Jr., W. S. W. McCarter and J. B. Sanborn. *Ind. Eng. Chem.*, 1944, 36, 99-109. The activation of trihydrate bauxites at temperatures up to 1600° F. has been studied with particular reference to the production of a highly efficient drying adsorbent. Data are presented to show the relationship between activation temperature, residual volatile matter content, surface area, dry gas capacity (a measure of the amount of water vapour held by the adsorbent up to the point where it just permits water to appear in the gas passing from it), and equilibrium capacity (a measure of the total amount of water vapour which can be removed by an adsorbent from a fluid stream under constant conditions of relative humidity, temperature and pressure). The mechanism of the thermal decomposition of bauxite is discussed with reference to the results of differential thermal and X-ray diffraction analyses. The maximum dry gas capacity is attained by activation at 700-750° F. This treatment reduces the volatile matter content of the mineral from about 28-30 to 6-8 per cent. Under optimum activating and operating conditions bauxite will adsorb 11-16 per cent. by weight of water before any moisture is detectable in the effluent. Activated bauxite may be regenerated repeatedly by heating at 300-500° F. Various other factors which influence drying efficiency, such as mesh size, moisture content of gas, velocity through adsorbent, adsorbent temperature, shape of adsorbent bed, and presence of impurities, are discussed. Some results obtained in the drying of gases at atmospheric and high pressures and in the drying of liquids are briefly discussed. C.

**Fibre Molecules: Coiling in Flowing Solutions.** W. and H. Kuhn. *Helv. Chim. Acta*, 1943, 26, 1394-1465 (through *Chem. Abstr.*, 1944, 38, 673<sup>9</sup>). Equations are derived that relate the amount of streaming birefringence or the direction of maximum refraction in flowing solutions of linear polymers to the degree of polymerisation (DP). The amount of streaming birefringence at limiting conditions is directly proportional to the DP and the direction at limiting conditions is proportional to (DP)<sup>2</sup>. Values for the DP calculated from these optical measurements agree excellently with values obtained from viscosity measurements (Staudinger). Data for DP determined with the ultracentrifuge are used for comparison. The agreement with data from viscosity or optical measurements is excellent, except when the DP is very high. It is suggested that this discrepancy exists because at high values the coiled molecules form a strongly felted structure which immobilizes solvent between parts of the network. The theoretical treatment used in deriving the equations referred to above is valid only when the surrounding liquid flows freely between the fibre molecules, as is the case when the DP is relatively low. C.

**Potato Starch Pastes: Viscosity.** P. E. Meiss, R. H. Treadway and L. T. Smith. *Ind. Eng. Chem.*, 1944, 36, 159-163. The influence of the conditions of preparation and measurement on the apparent viscosity or consistency of starch paste is discussed. The Brabender Viscograph is briefly described and an account is given of investigations made with this instrument. Although drying starch to nearly zero moisture content causes considerable lowering of paste consistency, the oven drying of wet starch to the air-dry moisture range, at temperatures below 90° C., does not result in such an effect. Consistency/temperature curves are given for two pastes made from the same starch, one using distilled water and the other using tap water. The lower consistency of the latter is attributed to soluble material in the tap water. The removal of soluble impurities from starch by washing is discussed and it is shown that the change in the consistency/temperature curve produced by washing gives indications of the causes of low consistency. The results of examinations of 24 samples of

potato starch produced in factories in the United States during the 1941-42 season are reported. It is pointed out that a sample of average-quality potato starch should have an ash content of about 0.35 per cent., low acidity, a  $pH$  near the neutrality point, high reflectance, and a paste consistency/temperature curve in which a peak occurs below the boiling point and which remains substantially unchanged when the sample is washed with distilled water. The influence of manufacturing methods and of the water used on the quality of starch is considered. Experiments indicated that the method of purification had no bearing on particle-size distribution. C.

**Starch and Bentonite Suspensions: Viscosity; Effect of Electrolytes.** A. v. Buzágh. *Kolloid Z.*, 1943, 103, 119-126 (through *Chem. Abstr.*, 1944, 38, 289<sup>9</sup>). The viscosities were measured at different concentrations and in the presence of various amounts of electrolytes such as Na, K, Ba, Cu, Al and Th chlorides, K and Mg sulphates, and K phosphate, ferricyanide and ferrocyanide. The results were compared with results obtained on quartz suspensions. In general, starch and quartz suspensions have similar properties, except that in starch both ions affect the viscosity, whereas in quartz only the cations have a pronounced effect. Bentonite suspensions, being hydrophilic, behave differently. C.

**Colour Harmony: Effect of Area.** P. Moon and Domina E. Spencer. *J. Optical Soc. America*, 1944, 34, 93-103. The scientific formulation of colour harmony is extended by taking into account the effect of area. It is found that a pleasing balance among colour patches is obtained when the scalar moments about the adaptation point in  $\omega$ -space are equal for all the patches. Other pleasing balances are obtained when the scalar moments of the various colour patches are simple multiples of each other. The balance point in  $\alpha$ -space of a system of colour patches gives a measure of the over-all colour effect of the design and, by choice of a proper balance point, the artist can emphasize a desired psychological effect. Moments in colour space are treated most simply by means of weighted points. The mathematics of this subject is developed, and the calculated areas for harmonious effects are tabulated for a large number of examples. Practical application of this system by the designer is briefly explained. C.

**Dyes and Pigments: Spectrophotometric Formulation.** R. H. Park and E. I. Stearns. *J. Optical Soc. America*, 1944, 34, 112-113. Methods are presented whereby the formulation of colorants needed to effect a visual colour match of a given standard may be computed from spectrophotometric measurements of the colorants and standard. C.

**Machinery Testing Devices.** Institution of Mechanical Engineers. *Engineer*, 1944, 177, 237-238, 257-258. Abstracts are given of papers presented at a symposium on modern aids in the investigation of materials, mechanisms and structures, including (1) electrical resistance wire strain gauges, (2) measurement of displacement and strain by capacity methods, (3) measurement of strain in components of complicated form by brittle lacquer coatings ("Stresscoat"), (4) high-speed cinematography, (5) temperature-indicating paints, and (6) study of internal stress in a metal by X-ray diffraction. C.

**Wool Wax Alcohols: Properties, Composition and Utilisation in Medicine.** E. S. Lower. *Mfg. Chem.*, Aug. and Sept., 1943. W.

**Thermally-shortened Keratin Fibres.** H. Zahn. *Naturwissenschaften*, 1943, 31, 137-139 (through *Chem. Abs.*, 1943, 37, 6285). Pure white horse hairs were heated by a Bunsen flame, shrunk 32 per cent., increased in thickness 58 per cent. and studied by X-ray. The diagram has 3 isotropic rings, 3.78, 4.60 and 10.1 Å, similar to that of the keratin decomposition product (*these Abs.* 1941, A601),  $d$ -keratin. Both materials are  $\beta$ -keratins. Measurement of swelling anisotropy shows the same change, only 2.9 for the heated hair, 16.4 for the original. During the heating process the weight loss is 2.6 per cent., the cystine content decreases 10 per cent., the isoelectric point changes little and the alkali solubility increases. The process is a "super-contraction" (Astbury and Woods, *these Abs.*, 1943, A60). Hairs will shrink in their own sorption moisture by rapid heating. The same effect is not found if water is absent. Heating in water at 130° for 2 hr. gives a 25 per cent. shrinking with formation of  $\beta$ -keratin, likewise heating at 150° in moist glycerol. W.

**Stretched and Super-contracted Human Hair: Microscopic and Hygroscopic Investigations.** T. Lochte and H. Brauckhoff. *Biochem. Z.*, 1942, 312, 41-59 (through *Chem. Abs.*, 1943, 37, 6290). The observations of Astbury and Woods (*these Abs.*, 1934, A60) on the extensibility of human hair were confirmed. It has been stated that red hair contains an unusual keratin, but no differences were observed between red and other hair, when subjected to humidity changes, under tension. Super-contracted hair is not as extensible in a normal atmosphere as the original hair. W.

**Sheep Maggots: Field Experiments on Control.** W. R. Angus, I. Thomas and O. G. Williams. *Ann. Appl. Biol.*, 1943, 30, 164-169 (through *Exp. Sta. Rec.*, 1944, 90, 233). In field experiments on about 4,700 sheep at about 40 different farms in N. Wales, crutching was the most effective control measure for lambs. Regular dipping with commercial arsenic-sulphur dips gave reasonable control except during adverse weather conditions. Dipping with zinc arsenite or with calomel proved, on the whole, less effective than dipping with commercial dip. An addition of calomel to commercial dip was more effective than commercial dip alone. Preliminary observations are given on the variation of the surface tension and viscosity of the dipping fluid as the number of sheep passing through the dip increased. W.

**British Sheep Blowflies: A Survey.** J. MacLeod. *Bull. Entomological Res.*, 1943, 34, 65-88, 95-111. W.

#### PATENTS

**Powder Specific Surface Determining Apparatus.** H. Heywood. B.P.560,037 of 10/9/1942:16/3/1944. Apparatus for examining suspensions comprises reflectors, mirrors, lenses and/or prisms operative for constraining separate beams of light from a common source to pass through respective test cells or spaces or through standard and test cells or spaces, respectively, and light-reflecting means for causing the beams issuing from the cells or spaces to be projected for comparison on to separate regions of an eyepiece, a graded light filter being movable in one of the beams to cause the intensities of the beams of light directed on to the eyepiece to be made equal to each other, and provision being made by which the amount of movement of the graded light filter may be used as a measure of the intensity of the light passing the cell or space under test. For the determination of the total specific surface or the particle size distribution, a suspension of the powder is placed in a test cell and a standard or comparison cell contains clear liquid of the same kind as that in which the powder is suspended. The graded light filter is suitably coupled with a pointer movable over a scale indicating optical densities. C.

**Carboxyethyl Cellulose Ether: Preparation.** Röhm & Haas Co. U.S.P. 2,332,048. A carboxyethyl ether of cellulose, soluble in water, is obtained by the treatment of cellulose at 5-35° C. with 10-40 per cent. alkali hydroxide and acrylonitrile in roughly equivalent proportions (based on the glucose unit). C.

**Cyanoethyl Cellulose Ether: Preparation.** Röhm & Haas Co. U.S.P. 2,332,049. A cyanoethyl cellulose ether, soluble in organic solvents, is obtained by treating cellulose at 0-30° C. with 10-30 per cent. alkali and 2-3 mol. proportions of acrylonitrile, based on the glucose unit. C.

**Alkali Metal Chlorites: Preparation.** Mathieson Alkali Works, Inc. U.S.P. 2,332,180, 2,332,181. (1) Chlorine dioxide is absorbed in an aqueous solution of an alkali metal bicarbonate containing hydrogen peroxide. (2) Chlorine dioxide is prepared by the reaction of a chlorate with mineral acid (*pH* not much above 1) and hydrogen peroxide at a temperature not much above 70° C. C.

#### 10—ECONOMICS

**Textile Wholesale Prices, March, 1944.** *Bd. Trade J.*, 1944, 150, 141. The wholesale price index numbers for March are Cotton 139·5, Wool 183·6, Other textiles 134·2 (1930=100). C.

**American Textile Industry: Future Prospects.** D. G. Woolf. *Textile Research*, 1944, 14, No. 1, 2-7. A discussion of the outlook in the textile industry, the certainty of a growth in research in the near future, research in connection with the war effort and its influence on the type of textiles available after the war, problems of the textile industry in the immediate post-war

period, new technical developments, textile raw materials of the future, the emergence of new finishes, the development of new equipment, and the economic outlook. C.

**Cotton, Yarn and Cloth: Controlled Prices, April, 1944.** W. H. Slater. *Textile Weekly*, 1944, 33, 584. New tables are provided with which to correct the author's previous lists so as to allow for the change in the Cotton Control basis from 7·80 to 12·75 d. per lb. for the price of American cotton. C.

**Indian Cotton Cloth: Production and Consumption.** M. Masani. *Indian Textile J.*, 1943, 54, 4-7. A popular account is given of the growth of the cotton industry in India with special emphasis on "clothing 400 millions." The following charts are noteworthy. (1) A map showing the concentration of the industry. (2) Graphs of numbers of operatives, mills, spindles and looms from 1879 to 1941. (3) Histograms of cloth consumption per head in India from 1915 to 1941. (4) Histograms of cloth consumption per head in 1936 for India and some other countries, Europe being represented only by Sweden and Ireland, and North America by Canada. C.

**Raw Cotton: Prices.** *Cotton (M/cr.)*, 1944, 49, No. 2403, 4; 50, No. 2404, 5. (1) Tables are given showing the controlled prices of American, Brazilian, African, Egyptian, Sudan and Peruvian raw cottons as from April 17th, 1944. (2) Official prices for various marks of Egyptian cotton are tabulated. C.

**Rayon: World Production and Consumption, 1942.** *Silk and Rayon*, 1944, 18, 263-264. The best available estimates of continuous filament and rayon staple production in 1942 are tabulated for 25 countries. The annual *per capitum* consumption of rayon, based on figures for 1937/9, is given as Germany 6·49 lb., Japan 5·30, Italy 3·82, Australia 3·08, United States 2·83, United Kingdom 2·44, New Zealand 2·43, Switzerland 1·97, Sweden 1·91, Canada 1·76, Czecho-Slovakia 1·73, Netherlands 1·36, Belgium 1·30, France 1·24, Denmark 1·14, Trinidad 1·04 and Eire 0·80 lb. The state of trade and post-war expansion are discussed. C.

**British Cotton Industry: Planning.** "*Times*" *Trade & Engineering*, 1944, 54, April, p. 42. The special committee appointed by the Cotton Board for dealing with post-war problems has asked the Government for an assurance that the appointment of a post-war Cotton Board will be made before the present Cotton Control is abolished. The certainty of a serious shortage of operatives in the industry after the war has directed special attention to the urgency of carrying out reforms which will make work in the mills more attractive. A committee of recruitment and training has already been appointed and a special department of the Cotton Board set up to administer the plans and policy of the committee. The intention is not only to ensure regular and interesting work at good wages, but also to offer good prospects of promotion to ambitious juveniles. The most recent development is the institution of a training scheme for foremanship and other mill executive positions and over 1,300 enrolments have been made for a course of 12 lectures. The total general wage advances for workers in the manufacturing section since the outbreak of war amount to 35 per cent. for cost of living, plus 9/- a week flat increase. It is expected that joint meetings will be held in the near future to discuss a starting-point system of wages for weavers. The sub-committee appointed by the Cotton Spinners' and Manufacturers' Association to investigate methods of wage payments and conditions of work in the weaving section has suggested a number of improvements which are likely to lead to higher efficiency and better relationships between employers and workpeople. A good response has recently been made to the request of the Cotton Controller for a resumption of overtime working in spinning mills. C.

**International Trade: Changing Outlook.** *Planning*, 1944, No. 219, 24 pp. A survey is made of pre-war trends in international trade and the economic effects of the war are discussed. The following conclusions are drawn:—(1) Exports are essentially a means of obtaining necessary or desirable imports, and should not be used primarily as a means of creating home employment. Both export and import policy should be deliberately related to a nation's Balance of Payments and its long-term foreign lending and borrowing. (2) Trade restrictions

and bilateralism were a symptom, more than a cause, of the decline in world trade after 1929. Post-war policy should aim at a continuing expansion of effective world demand, making full use of the world's man-power and resources. (3) Multilateral trade, whilst creating the necessary conditions for obtaining the greatest possible advantages from international trade, also heightens the economic interdependence of nations. A restoration of multilateral trade requires (a) an efficient international monetary exchange clearing system in which all nations have complete confidence, (b) the maintenance of full employment within national economies, and (c) the maximum attainable measure of political security. (4) Failing the establishment of a universal multilateral system of trade, the "low-tariff club" represents a means by which nations most dependent on international trade can secure the benefits of multilateralism on a limited scale. (5) "Lend-Lease" is essentially a war-time method of international exchange, and is unlikely to continue after the immediate post-war period of scarcities. International trade, however, must have a monetary exchange clearing system that is at once more flexible than the Gold Standard and more stable than freely fluctuating exchanges. (6) World prosperity, like peace, is indivisible. (7) Great Britain's major problem in the field of foreign trade after the war is to increase its visible exports very considerably in order to repair the inroads which the war has made into its invisible exports and overseas investment income and to maintain the volume of imports vital to its standard of living. The form of policy appropriate will inevitably be affected by the economic policies adopted by the rest of the world, and in particular by those countries with the largest share in international trade. C.

**Spanish Textile Industry: Development.** "*Times*" *Trade & Engineering*, 1944, 54, April, p. 18. According to statistics published by the Spanish Textile Syndicate, production of fabrics in 1943 amounted to 392,500,000 metres, an increase of 75,000,000 m., compared with 1942. This total consisted of 300,000,000 m. cotton fabric, 48,000,000 m. silk and 44,500,000 m. woollen fabric. About 11,430 enterprises, employing about 450,000 people, are engaged in the textile industry. In 1940 production of cotton amounted to over 10,000 bales, and in 1942 to 19,666 bales, and it is hoped that the figure for 1943 will be similar to that of 1942. The production possibilities of Spain have been estimated at 120,000 bales. In the provinces of Cordoba and Seville, the cotton growing areas, numerous mills have been erected in the last few years. Others are being built at Utera, Cordoba, Badajoz, Careres and Malaga with a capacity of 80,000 bales a year. Breeding of silkworms in Spain has increased considerably in the course of the last few years. This year's yield is estimated at 500 tons of cocoons, compared with 407 tons in 1943. About 80 per cent. of the entire production comes from the province of Murcia. The production of the silk industry has increased from 46,000,000 m. in 1942 to 48,000,000 m. in 1943, a figure which is 50 per cent. higher than in 1935. It is expected that once all measures taken by the authorities to improve silkworm cultivation in Spain have been completed Spain will be able to meet home requirements. C.

**Wool Products: Labelling; Australian Legislation.** "*Times*" *Trade & Engineering*, 1944, 54, April, p. 14. At the instance of the Commonwealth Government, the Australian States have agreed to introduce legislation providing for the uniform labelling of textiles to ensure that fabrics shall not be offered to the public as woollens unless they contain at least 92 per cent. of wool. The United States Wool Products Labelling Act, 1939, has been suggested as a model for uniform Australian legislation. A difficult problem is to ensure that imported piece-goods containing synthetic fibres carry into made-up garments the labels which Customs regulations require to be affixed to them on entry into Australia. One of the post-war objectives of the Commonwealth Government is the establishment of a textile college with research facilities to enable wool to hold its place against synthetic fibres produced from pulp, cotton or other cellulose base. C.

**Wool: Post-war Marketing.** G. E. Scott. *Wool Rec.*, 1944, 65, 172, 174, 176. Three principles are discussed: market stability by maintaining constant relationship between supply and demand with the resultant economic price; a system which permits and encourages continuous adaptation of standards and sources of supply; enterprise to experiment and pioneer. With the exception of

the indefinite contract, the pre-war system of wool marketing has proved its value, and should be reconstituted as soon as possible after the war. W.

**Wool Marketing Experiment: A Record of the Operations of the British Australian Wool Realisation Association.** G. J. Blau. *Wool Rec.*, 1944, 65, 333, 335, 337-8. W.

**"Wool in the World of To-morrow!"** F. Hopkinson. *Wool Rec.*, 1944, 65, 341, 343, 345. Future possibilities are discussed in regard to raw materials, machinery, and the production of yarns and fabrics. W.

**"The Truth About Wool."** H. F. Tomalin. *Wool Rec.*, 1944, 65, 171. It is suggested that the Board of Trade ruling on the term "wool yarn" should be changed, and that all members of the wool trade should contribute towards advertising wool and its basic value for clothing. W.

**Wool: Advertising Valuable Properties.** D. R. Christie. *Wool Rec.*, 1944, 65, 171. A plea for the more extensive advertising of the more valuable properties of wool fabrics, for the development of processing for water-proofing fabrics for post-war trade, and for the fixing of standards of manufacture to prevent misdescriptions. W.

**The Wool Industry and the Post-war World.** I. C. Ross. *Pastoral Rev.*, 1943, 53, 802-3, 1944, 54, 14-15. The possibilities of increasing the efficiency of wool production are discussed. Responsibility for textile research in Australia must be accepted, the prestige of wool maintained, and new markets developed. The scale of present-day research activities is hopelessly inadequate in relation to the gravity of the problems and the importance of the industry, and the immediate setting up is advocated of a central authority in Australia, to administer funds for biological, textile and economic research and for promotion and publicity. W.

**Pure Wool or Not?** W. R. Lang. *Pastoral Rev.*, 1944, 54, 18-19. The confusion arising from present-day descriptions of wool goods can only be removed by honest labelling, which should cover general serviceability of the fabric as well as fibre content. Simple tests are described by means of which the average customer can supplement the information given by handle and appearance of the fabric. W.

**What is Wool?** N. G. Baguley. *Text. Merc.*, 1944, 110, 239. The Retail Trading Standards Association is in favour of restricting the use of the word "wool" to the description of a substantially all-wool article, and of declaring the constitution of goods sold as "woollen." W.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY AND EDUCATION

**Cardroom Workers: Training.** *Cotton (U.S.)*, 1944, 108, No. 1, 109-112. The writer explains his method of starting learners at work and provides copies of (1) a daily work progress record and (2) a learner's work progress sheet. The latter sets out clearly how the learner will be paid and provides tables in which the manager enters week by week the number of frames run (drawframes and fly frames) and the percentage efficiency reached. It is explained that the minimum rate of pay—a time rate—will be changed to a piece rate as soon as the efficiency reaches the requisite high level. The learner signs a declaration of understanding of the progress sheet. C.

**Industrial Workers: Fatigue.** P. S. Florence. *Nature*, 1944, 153, 363-364. Experience in the study of industrial fatigue is discussed and it is suggested that "social medicine" can be regarded as an extension of such work and can be defined as the study of variations in human health and efficiency with variations in social living and working conditions. Such a study, aiming at the scientific observation of social norms of behaviour, can and (where laboratory experiment is impossible) must be based on statistical measurement and summarization. Full exploration must be made of the possibilities of vital statistics as a measure of health and efficiency as well as statistics of social conditions. Conditions relating to psychological social and family relationships have proved particularly difficult to observe and measure in fatigue studies and are likely to do so in social medicine. Further, different classes of persons will react dif-

ferently to similar conditions according to their heredity, sex, age, education and past experience. A chair of social medicine should, therefore, in a fully developed school, be supported by a staff that includes experts in demography and social statistics, in social psychology and anthropology, and in social biology. A general scheme of study for social medicine is outlined, and classical and recent research in social medicine is briefly reviewed. C.

**Knitting Operatives: Training.** H. E. Reed. *Textile World*, 1943, 93, No. 4, 108-109. The problem of training new employees in American knitting mills is discussed and the schemes adopted by some representative hosiery and underwear firms are described. C.

**Factory Noise: Reduction.** H. J. Sabine and R. A. Wilson. *J. Acoust. Soc. America*, 1943, 15, July, 27-31 (through *Sci. Abstr.*, 1943, 46 A, 232). Noise-level measurements in 33 plants of diverse nature varied between 65 and 130 decibels, and in the majority from 85 to 105 db. Factors other than noise-level contribute to the discomfort of the worker, namely, reverberation and the spreading-effect of sound or the tendency of sound in a non-absorbent room to decrease at a slow rate with increasing distance from the source. Further, a machine operator is affected less by the sound of his own machine than by others near him. Conditions favourable to improvement are: wide spacing of machines, differing qualities of noise from various units, and intermittent operation of the machines. In rooms where the smallest floor dimension is at least several times the ceiling height, and having a sound-absorbent ceiling (coefficient at least 0.7), the intensity level due to one or more sources decreases at a constant rate over the entire area of the room. This rate varies inversely with the ceiling height and may be 0.2 to 0.4 db./ft. C.

**Philadelphia Textile Institute: Research Work.** H. W. Rose. *Textile Research*, 1944, 14, 42-46. The dual objectives of research, knowledge and education, and the value of applied research in textile schools are discussed, and a brief account is given of the research work being carried out in the Philadelphia Textile Institute. Industrial problems are brought to this Institute by manufacturers, mills, factors in the trade, and by the Government. The research projects are arranged through the dean, who determines whether and when the work can be undertaken. Since it is difficult to estimate the exact cost of a project, the contract usually provides for periodic payments for a definite time. The research work is conducted by the faculty in its spare time. If appropriate, students may assist, and in some exceptional cases a project becomes part of the work of an entire class. Some subjects of research are undertaken by the Institute without sponsorship in the course of its regular work. C.

**Research Associations: Expenditure.** *Chemistry and Industry*, 1944, 168. Figures are given showing (1) the approximate expenditure of the 18 grant-aided research associations for the year 1942-43, (2) the net output of the industries concerned according to the Census of Production, 1935, and (3) the amount expended by the research associations per £100 of output. Research Association expenditure in 1942-43 varied from £7,200 for the boot and shoe industry to £115,200 for the cotton, silk and rayon industry, the expenditures per £100 net output being £0.04 and £0.17, respectively. The lowest expenditure per £100 output was £0.01 in the Printing and Allied Trades, and the highest £0.63 in the Refractories industry. C.

# THE JOURNAL OF THE TEXTILE INSTITUTE

## ABSTRACTS

### 1—FIBRES AND THEIR PRODUCTION

#### (B)—ANIMAL.

**Sheep Scab: Elimination.** *Farmer & Stockbreeder*, 1944, 58, 658. If, in double-dipping areas, the first dip should be coloured bright yellow and the second bright red, this would facilitate the rounding-up of stray sheep, which are the potential scab-carriers. If the disease could be stamped out in this way, it is suggested that it might be worth while to suffer for a few years the inconvenience caused to the wool trade from coloured wool from scab areas. W.

**Tick-borne Diseases of Sheep: Occurrence and Control.** W. L. Stewart. *J. Min. Agric.*, 1944, 51, 23-27. W.

**Mammalian Hair: Morphology.** J. L. Stoves. *Nature*, 1944, 153, 285. Transverse sections are illustrated of the proximal and medial regions of guard-hairs from silver fox and kolinsky. The proximal regions show variation in fibre contour which occurs during atrophy of the hair root. W.

**Wool: Scale Structure.** W. B. Geiger. *Amer. Dyes. Rep.*, 1944, 33, 117-118; *Text. Res.*, 1944, 14, 82-85. The scale material left intact after dissolving the interior of the fibre (see these *Abs.*, 1942, A 199) has been reduced, alkylated and treated with pepsin by methods similar to those previously described (see these *Abs.*, 1941, A570 and 1943, A168). It is composed largely of protein and contains the same amino acids as untreated wool, but in different proportions, having more sulphur and serine and less nitrogen, arginine and tyrosine. The reduced scale material was more stable to enzymes and alkalis than reduced wool. W.

#### (C)—VEGETABLE

**World Cotton Crop: Production, 1943-44.** *Textile Weekly*, 1944, 33, 666. The output of cotton in the past three seasons, and forecasts for 1943-44, are tabulated for each country producing more than 25,000 bales and for the 35 other countries in which small crops are grown. The crop for the current season is expected to reach 26 million bales. C.

**Cotton Bales: Sampling.** R. W. Mitchem. *Textile World*, 1944, 94, No. 3, 88-89. Attention is called (with illustrations) to the dilapidation of cotton bales and consequent loss due to cutting the cover for taking a sample. The bill for new bagging in the United States is nearly \$10 million annually, though jute or cotton covers should last 25-35 seasons if stored in dry places and not cut. The writer suggests that a licensed grader and cotton classer should be attached to each ginnery to see that a duplicate sample of the cotton of, say, 7 lb. is fastened under the middle bale ties in a waterproof paper envelope. Sub-samples could be withdrawn but not replaced and the bale cover would be preserved. C.

#### (D)—ARTIFICIAL

**Cellulose: Preparation from Wood, Plants and Lignites.** A. W. Sohn. *Zellwolle, Kunstseide, Seide*, 1943, 48, 78 (through *Chem. Zentr.*, 1943, i, 2652 and *Chem. Abstr.*, 1944, 38, 1109<sup>5</sup>). By means of sodium chlorite, celluloses can be prepared that contain little lignin, an optimum amount of hemicelluloses, and an unchanged degree of polymerisation. Thus wood yields a white cellulose of maximum strength. Sodium chlorite is still more suited to treatment of annual plants, when combined with alkali pre-treatment or after-treatment. Pre-hydrolysed wood is improved only slightly by sodium chlorite; the improvement is greater on alkali after-treatment. Lignite when treated with sodium

chlorite gives satisfactory yields of a product that has a degree of polymerisation of 800, and contains uronic acids but little pentosans. C.

**Unbleached Pulp; Action of Nitrogen Dioxide on —.** E. Heuser and C. M. Sigvardt. *Paper Trade J.*, 1944, 118, TAPPI, 82-84. Samples of unbleached pulp of 1 and 6 per cent. moisture contents were treated with nitrogen dioxide at room temperature for periods of 15, 40 and 80 min., and an aqueous pulp suspension of 3 per cent. consistency was treated for 80 min. at 20° and 90° C. Lignin and nitrogen contents, permanganate numbers and viscosities were determined after washing with water and after extraction with caustic soda solution. The results show that delignification and degradation occurred simultaneously, but the latter proceeded at a somewhat slower rate than the former. The lignin content (1.80 per cent.) of the slush pulp treated for 80 min. at 20° C. and washed with water was of the same order as that of the 1 per cent. and 6 per cent. moisture pulps treated for 80 min. at the same temperature, but treatment for 80 min. at 90° C. followed by washing with water reduced the lignin content to 0.60 per cent. Thus temperature appeared to be the most important factor for delignification. All the treated samples contained measurable quantities of nitrogen. The results of these tests support the suggestion that the action of nitrogen dioxide upon unbleached pulp proceeds in two phases, nitration of the lignin residue and solubilization of the nitrolignin by oxidation. C.

**Viscose Staple Rayon: Spinning under Tension.** H. vom Hove. *Zellwolle, Kunstseide, Seide*, 1942, 47, 718-720 (through *Chem. Abstr.*, 1944, 38, 1109<sup>1</sup>). Replacement of mechanical stretching by tension produced by a current of the coagulating liquid is discussed; the alkali resistance of stretched staple fibre is greater than that of normal staple fibre. C.

**Viscose Rayon Factory: Hazards.** Alice Hamilton. *Bull. U.S. Dept. of Labor Division of Labor Standards*, 1940, No. 34, 79 pp. (through *Bull. Hygiene*, 1944, 19, 212-213). Risks of poisoning from carbon disulphide and from hydrogen sulphide are present in the viscose rayon industry. In one plant 143 p.p.m. of carbon disulphide were found in the air at the churn door and 139 p.p.m. in the centre of the room. By careful control the concentrations can be brought below 15 p.p.m. In the spinning process, acid spray, carbon disulphide and hydrogen sulphide are evolved. Measures for the control of acid spray also control the two toxic gases. Cases of conjunctivitis give evidence of the presence of hydrogen sulphide. Fumes of carbon disulphide and hydrogen sulphide are evolved in reeling, washing, desulphurising and bleaching processes. The toxic effects of daily exposure to carbon disulphide are apparent before acute symptoms develop though cases of sudden insanity have occurred. The peripheral nerves of the ear, eye or muscles may be affected. The most striking effects of carbon disulphide poisoning are upon the brain. The mental symptoms vary from simple irritability and depression to insanity. If the basal ganglia are involved Parkinsonian palsy occurs. Details of 27 cases are quoted. Poisoning by fumes of hydrogen sulphide is a less serious hazard. A few cases of acute intoxication have been reported, but the patients have generally been resuscitated. The milder troubles are inflammations of the eyes which subside in 48 hours, although in severe cases corneal involvement may develop. The following limiting concentrations are recommended: for carbon disulphide 20 p.p.m. and for hydrogen sulphide 20 p.p.m. for eight hours, 30 p.p.m. for one hour. C.

**Interpolyamide-ester Nylons: Production and Properties.** *Silk & Rayon*, 1944, 18, 544-548. Attention is called to the possibility of producing a wide range of nylons by condensing the dibasic acid component with a glycol as well as a diamine (see B.P. 535,262; E. I. Du Pont de Nemours Co.). Tables and curves are reproduced to show how the melting points, hardness and elasticity of the nylon vary with the proportion of glycol in the batch. C.

**Nylon, Acetate and Viscose Rayons and Vinyon: Recent Developments.** (1) R. A. Ramsdell. (2) H. De Witt Smith. (3) & (4) F. Bonnet. *Amer. Dyes. Rept.*, 1944, 33, 121-123, 124-125 and 128, and 126-127, 127-128. (1) A review of the development of nylon, progress in methods of dyeing and finishing, uses and advantages of nylon yarn, and the use of nylon for the production of coated materials, bristles and other articles. (2) Figures showing recent increases in

the production of acetate rayon in the United States are given, types of continuous filament acetate yarns now being produced and their physical properties are described, characteristics and uses of acetate staple fibre are outlined, special types of textile fibres employing cellulose acetate are mentioned, and recent developments in dyeing and finishing, particularly improvements in light fastness and fume fastness and the development of discharge printing, are reviewed. (3) A brief discussion of the development of strong continuous filament viscose rayon yarns and special yarns for special purposes, and of the characteristics and uses of the various types of viscose staple fibre. (4) The properties and uses of Vinyon are briefly described. C.

**Hot Water-resistant Casein Fibres: Production.** A. M. Kats and G. A. Arbuzov. *J. Applied Chem. (U.S.S.R.)*, 1943, 16, 134-142 (through *Chem. Abstr.*, 1944, 38, 1371<sup>2</sup>). With increased temperature and duration of tanning and higher formaldehyde concentration, the binding of formaldehyde by casein fibres increases; however, increased formaldehyde content lowers the fibre strength. The best results were obtained with formaldehyde concentration of 50 g./l., sodium sulphate 150 g./l., temperature 25°, duration 8-10 hours, pH 4.5-5. Retanning with formaldehyde of fibre tanned either with formaldehyde or chrome increases both dry and wet strength. In chrome tanning, increased chromic oxide concentration, basicity, temperature and duration lead to higher chromium concentration on the fibre; after chrome tanning and washing, the fibre should be neutralised with alkali salts. C.

**"Avisco" Rayon Staple: Properties.** American Viscose Corporation. *Silk and Rayon*, 1944, 18, 375. It is announced that a strong type of viscose staple is on the market in 1.0 den. and various lengths. The material has been spun in counts as fine as 300s. C.

#### PATENTS

**Cellulose and Lignin: Recovery from Wood.** R. H. McKee (New York). B.P.560,492 of 30/6/1942:6/4/1944. Wood or other lignified cellulose material is digested for about 12 hours at a temperature of 150° C. with a hydrotropic solvent comprising an aqueous solution of a readily soluble salt of an aromatic acid derived from a single benzene ring. At the end of this treatment the cellulose is filtered from the accompanying liquor, which contains lignin in solution in the state in which it originally occurred in the wood. The cellulose is washed, preferably with the hydrotropic solvent in diluted condition, and may then be bleached by customary methods. The cooking solution, after the separation of the cellulose therefrom, is used again, preferably six or seven times, after which it is diluted with at least three times its volume of water to precipitate the lignin. The lignin is filtered and washed, and can then be used for various industrial purposes. C.

**Vinyl Resin Mono-filaments: Production.** American Viscose Corporation and K. Heymann. B.P.560,535 of 26/8/1942:7/4/1944 (Conv. 1/10/1941). A bundle comprising thermoplastic vinyl resin filaments which have been stretched in excess of 50 per cent. at some time during their production is twisted and converted directly by heating, while taut, into a unitary filament having to all appearances the structure of a true mono-filament. Preferably, a twist of from 3 to 10 turns per inch is employed to obtain the greatest uniformity and resistance to abrasion in the product. A fluid heat transfer medium is preferred. The bundle may be treated in the form of an unwound yarn or in package form. C.

**Rayon Spinning Box.** American Viscose Corporation. B.P.560,616 of 10/2/1943:12/4/1944 (Conv. 18/3/1942). A spinning box comprises a hub portion having a central bore adapted to receive driving means, and a member carried by the hub portion and arranged to be actuated by centrifugal force to effect positive coupling between the spinning box and the driving means whereby the spinning box is positively driven. C.

**Chlorinated Vinyl Co-polymer Filaments: Production.** American Viscose Corporation. B.P.560,660 of 27/1/1942:14/4/1944 (Conv. 22/7/1941). A solution of a co-polymer of vinyl chloride and vinyl acetate having a molecular weight of at least 1,500 and containing about 80-95 per cent. by weight of vinyl chloride, is chlorinated until the final product has a total Cl content of about 58-64 per cent. by weight whereby the product acquires a shrinkage tem-

perature range above 100° C. and improved solubility characteristics. The shrinkage temperature range is defined as the 5° C. range of temperature through which 5 per cent. shrinkage occurs as a filament is subjected to gradually increasing temperatures. The chlorinated co-polymer is precipitated from solution, washed, and, if desired, dried. The product may be dissolved and spun by wet or dry processes, and the filaments may be stretched at temperatures about 40-50° C. above their shrinkage temperature range. C.

**Rayon Staple Cutting Apparatus.** American Viscose Corporation and H. H. Bitler. B.P.560,670 of 31/8/1942: 14/4/1944 (Conv. 12/3/1942). In apparatus for cutting rayon staple of the kind in which a bundle of continuous filaments is subjected to successive severing operations, there are provided means for feeding the bundle at a constant speed, a number of cutting elements having different spaces between them for cutting the bundle into fibres of various lengths, and means for adjusting the distance between the cutting elements. The cutting elements may be disposed at unequal distances apart about the periphery of a rotatable member. C.

**Polymeric Urea Derivatives: Production.** H. Dreyfus. B.P.560,784 of 23/1/1939:20/4/1944. Condensation polymers of high molecular weight suitable for the production of filaments, films, and coating compositions are produced by heating certain organic compounds containing only two reactive radicals of which at least one is the radical of urea, thiourea or a similar compound, e.g. N:N'-dimethylurea or N-methyl-thiourea, and has the formula  $-NR.CX.NHR_1$ , where R and  $R_1$  are each H or a hydrocarbon radical and X is O or S. One or more organic compounds each containing only two reactive radicals, each of which has the formula  $-NR.CX.NHR_1$ , may be heated until a product having filament-forming properties is obtained, or an organic compound containing only two reactive radicals, each of which is a primary or secondary amino group, may be heated with an organic compound containing only two reactive radicals, one of which has the formula  $-NR.CS.NHR_1$  and the other has the formula  $-NR.CX.NHR_1$ . The compounds employed are preferably aliphatic compounds particularly ones in which the pairs of reactive radicals are linked by chains of methylene groups or at least attached to methylene groups. C.

**Linear Polymeric Urea Derivatives: Production.** H. Dreyfus. B.P.560,785/6 of 23/1/1939:20/4/1944. (1) Linear polymeric compounds of high molecular weight suitable for the production of filaments, foils, films and other articles are produced by linking up molecules of simple organic compounds by heating them so as to effect reaction between radicals having the formula  $-NR.CO.NHR_1$ , where R and  $R_1$  each represent a hydrogen atom or a hydrocarbon radical, i.e. radicals of urea and hydrocarbon substitution derivatives thereof, and hydroxy groups present in the organic molecules. Each of the compounds employed contains in the molecule two and only two radicals which are reactive under the conditions employed for the production of the polymer. Preferred compounds are aliphatic compounds in which the reactive radicals are linked by methylene groups, e.g. trimethylene, tetramethylene, hexamethylene and decamethylene di-ureas, the corresponding glycols and the corresponding hydroxy-ureas. In order to obtain products having suitable properties for the formation of filaments, it is in general necessary to continue the reaction until the polymer has an average molecular weight of 6,000 to 10,000 or more. Filaments, films and similar products formed from the polymers may be cold-drawn or stretched, either continuously with their production or subsequently thereto. (2) Linear polymeric compounds of high molecular weight suitable for the production of filaments, films, coating compositions and other articles are produced by heating a diamine with an organic compound containing only two reactive radicals, one of which is a carboxylic acid radical or amide-forming derivative thereof and the other of which is a radical having the formula  $-NR.CO.NHR_1$ , where R and  $R_1$  each represent a hydrogen atom or a hydrocarbon radical, heating being continued until a product having film-forming properties is obtained. Each of the compounds employed contains only two radicals which are reactive under the conditions employed for the production of the polymer. The urea acids and their derivatives, which it is preferred to employ are those characterised by a chain consisting of methylene groups linked at one end to a radical of urea or a derivative thereof and at the other end to a carboxylic acid radical or an amide-forming derivative thereof. C.

**Staplisled Rayon Yarn: Production from Continuous Filaments.** J. Mackie & Sons Ltd. and J. P. Mackie. B.P.560,902 of 23/10/1942:26/4/1944. A machine for the manufacture of staplisled yarn from continuous filaments by a process of drawing and breaking the filaments and spinning the staple fibres as they are delivered includes feed rollers running at a low speed, breaking rollers running at a high speed, intermediate guiding and restricting means for controlling the sliver while it is being broken, and means for stretching the sliver before it is delivered to the feeding rollers in order to ensure that the filaments are delivered in a straightened and stretched form at the feed rollers, said means preferably comprising an additional pair of rollers with their nip at a distance of about a yard from the nip of the feed rollers, and either driven at a surface speed a little below that of the feed rollers, or subjected to drag by a braking device. The means for guiding and restricting the sliver between the feed rollers and the breaking rollers may include a restricting tube or channel, open at the top and preferably somewhat arched in form, which delivers the sliver to a travelling throat formed by a gap in the opposed surfaces of two geared rollers meshing together and rotating at a speed not much above that of the feed rollers. A set of faller bars may be used to keep the fibres straight just before they reach the point of entry to the gap between the breaking rollers. C.

**Viscose: De-aeration.** British Cellophane Ltd. B.P.561,050 of 16/7/1942:3/5/1944 (Conv. 18/7/1941). A continuous process of de-aerating aqueous viscous liquids, e.g. viscose, containing air or other gas, which comprises introducing the liquid continuously into a container, flowing the liquid in a layer or film of substantially uniform thickness in contact with the side walls of the container, subjecting the flowing film or layer of the liquid to a vacuum sufficiently high to cause the liquid to boil throughout the thickness of the layer or film, whereby removal of water together with the air or other gas takes place, is characterised in that the vacuum is controlled so as to maintain constant during the process the rate of removal of water per unit volume of liquid. C.

**Mechanical Cotton Picker.** A. W. Weems (Meridian, Miss.). U.S.P.2,333,965. A cotton harvesting machine has a bank of picker spindles revolving in horizontal vertically spaced tiers, a bank of stripper fingers that pass through the spaces between adjacent tiers of picker spindles, and means to produce air currents and suction to remove the lint from the spindles. C.

**Rayon Yarn Stretching Apparatus.** Celanese Corporation of America. U.S.P. 2,334,288. Apparatus for stretching a single end of rayon consists of a chamber containing a softening medium, means for feeding the yarn to the chamber and drawing it away, and means responsive to the degree of softness of the yarn for directing the path of the yarn on the withdrawing mechanism so as to change its speed of travel. C.

**Rayon Continuous Spinning and Treating Apparatus.** American Enka Corporation. U.S.P.2,334,325. Rayon is spun from a number of spinnerets in a bath and the threads are led in parallel rows to a set of pairs of upper and lower grooved rollers, there being as many grooves as threads. Groups of these rollers are provided with treatment tanks, and the bottom rollers are submerged in the liquid. The individual ends are wound into separate packages. C.

**Titanium Salt Delustred Rayon: Production.** American Enka Corporation. U.S.P.2,334,358. Dull rayon is spun from a cellulosic solution containing the titanium salt of a polymerised, unsaturated carboxylic acid having as substituents in the unsaturated aliphatic chain only hydrocarbon or carboxyl radicals or halogens; e.g. the copolymer of acrylic acid and vinyl chloride. C.

**Mineral Acid Solution of Cellulose: Spinning.** H. Fink, G. Rath and R. Hofstadt (Germany; vested in U.S. Alien Property Custodian). U.S.P.2,334,615. A suspension of cellulose in a mineral acid that is strong enough to cause swelling is fed continuously to an extruding device, together with sufficient mineral acid to complete the dissolution, the amount of solution formed in unit time being maintained equal to the amount passing through the spinneret. C.

## 2—CONVERSION OF FIBRES INTO FINISHED YARNS

### (A)—PREPARATORY PROCESSES

**Rayon Staple Opening Machines: Types and Beater Speeds.** *Textile World*, 1944, 94, No. 2, 109-110. Particulars of the sequence of opening and scutching machines, types of beater, and beater speeds are tabulated for ten different mills in the United States, together with information about the type of rayon staple and yarn count. The wide variations (e.g. beater speeds from 300 to 1050 r.p.m.) suggest the need for experiment to decide the best conditions. C.

**Cardroom Machinery: Modernization.** J. Buckley. *Textile Weekly*, 1944, 33, (1) 672-6, 710-4, 752-4; (2) 790-2, 824-6. (1) An illustrated report of a lecture on the construction, installation and efficiency of the following machines and appliances: (i) Sliver lap former, (ii) the Lap draw frame, (iii) Sliver cans, 12-in. diameter, and (iv) Platt's high-draft speed frame. A discussion is reported. (2) An illustrated report of another lecture in which the economy is stressed of the "combined operations" made possible by adopting the above machines. C.

**Roller Card for Long-staple Rayon.** Whitin Machine Co. *Textile World*, 1944, 94, No. 3, 105. An illustration is given of a new roller card for long-staple rayon (especially that over 2 ins.) which employs a double-lap feed, a set of six worker and stripper rollers instead of flats, a two-coiler front, and an improved bonnet to control the air currents. Under normal conditions the output is about 25 lb. per hour and the waste not more than 0.75 per cent. C.

**Post-war Woollen Carding.** G. Marshall. *Text. Mfr.*, 1944, 70, 165-167. Various arrangements of parts in woollen carding machines and their relative merits are discussed, particularly the Continental type of arrangements and a 4 lick-in section as used in worsted carding. For card clothing, thick felt fillet has many advantages. The use of low-quality wool oil does not necessarily save costs. Suggestions are made for obtaining a high level of efficiency on existing machinery, especially as regards worker and doffer speeds and the cleaning of card surfaces. W.

**Card Clothing: Efficient Use.** G. Marshall. *Wool Rec.*, 1944, 65, 550, 552; 554. English and Continental types of card clothing are compared. Continental-type cards are easier to keep clean owing to shorter length of wire above the foundation. Methods are suggested for obtaining maximum efficiency on English-type cards, e.g. by fitting dick-rollers on all doffers, by using efficient fly-strippers, by paying special attention to clothing of the swifts and by correct fettling. W.

**Maintaining Drawing Production.** *Wool Rec.*, 1944, 65, 625, 627. Drawing production can be maintained with a reduced number of operatives by using one end instead of two at the rover. Tables are given showing the necessary draft and doubling changes for 8- and 7-operation sets. W.

### (B)—SPINNING AND DOUBLING

**Cotton Mill Waste: Control.** T. Robinson. *Cotton (U.S.)*, 1944, 108, No. 2, 91-92. The writer advocates the appointment of a "waste control supervisor" whose duties are (1) to decide with foremen in all departments of the mill what types of waste are avoidable or not, (2) to maintain the waste percentages in various departments, (3) to arrange for the re-working or marketing of wastes and (4) to stimulate "waste consciousness." C.

**Cotton Mill Waste: Reduction and Utilization.** Joanna Textile Mills Co. (Goldsville, S.C.). *Textile World*, 1944, 94, No. 2, 112-113. Some particulars are given of the percentages of waste produced at various stages in the cardroom, spinning room, warping department, weaving shed and cloth room of an American mill consuming about 2000 bales of cotton per month. Figures are tabulated for 1940 and for 1943, after the introduction of various improvements that have brought the total waste from 11.32 to 9.56 per cent. The mill makes two special cloths from the waste, an osnaburg for bale covering and a tape frame blanket. The latter is plain woven from the same warp (lightly sized) and weft, 62 inches wide, 14 × 14, 0.7 yd. per lb., and is napped on the outer face. Fifteen yards are used for each squeeze roller and the blanket lasts for 8-12 weeks. The mill saves about \$500 per tape frame per annum by comparison with the conventional woollen blanket. C.

**Mule Spinner's Change and Wage Tickets: Application.** *Textile Weekly*, 1944, 33, 706-709. Hints are given on the rational use of change tickets and count determinations ("wrappings") for keeping records of the wheels employed in the spinning of a particular yarn and for calculating wages. C.

**Speed-frame Products: Effect of Doubling on Yarn Strength.** *Cotton (U.S.)*, 1944, 108, No. 2, 142-144. Further evidence is given that the Draper standards for yarn strength can be reached with few doublings. Particulars are given for two mills producing warp yarn ( $21\frac{1}{2}$ s) from 1-in. Middling cotton; in one mill there were only 16 doublings in the card room and double creeling in spinning, and in the other mill 32 doublings and single creeling. The count-strength products were the same and above the Draper standard. C.

**Woollen Fibres: Pot-spinning.** J. McCann. *Text. World*, 1944, 94, No. 2, 97-98. A pot-spinning frame for woollen-type yarns is described; it is not yet available commercially, but a 30-spindle frame has been demonstrated. The yarn is built up by centrifugal force inside the revolving pot. The pot is directly below the front roller nip and the yarn enters through a central tube. A fan built into the bottom of the pot sucks the yarn into the pot through this tube. Drafting is done in the way usual on woollen spinning frames, i.e. using a false twist tube, but the front rollers are of new design, and are in two pairs. In each pair one roller is cut away so that it contacts the other for only part of its revolution. The contacts on the two pairs are staggered so that only one pair grips the yarn at the same time. This allows twist provided by the false twist tube to flow and merge with that provided by the revolving pot. It is claimed that the machine gives high-speed production of large-size packages of unusually even and lofty yarn, and that defects are minimised by the very simple manner of piecing. Worsted, mohair, rayon and other fibres have also been spun by this method. W.

#### (C)—SUBSEQUENT PROCESSES

**Curling Yarn for Pile Fabrics.** "Concord." *Text. Merc.*, 1944, 110, 153-155, 159, 179-180, 220, 223. Types of curl imparted to animal fibre yarn are described, an irregular pattern giving a better imitation of the animal pelt. The Broadbent continuous yarn curling machine reproduces indefinitely any curl pattern on warp of the same kind, and has a large output for a low labour cost, as compared with hand-curling. The importance is emphasised of the boiling or setting operation, the best apparatus for this being a vessel fitted with a rotatable container for the stock, a dyeing machine of the Klauder-Welldon type being suitable, if it is used for no other purpose, and if the container is geared down to rotate at a single rev. every 10 min. Soft water must be used. The duration of the process varies from 1-4 hr. After boiling, the fibres are rapidly chilled to set the twists, and the stock is dried. The final operations are opening and sizing. The goods when woven are pressure-steamed in a cottage apparatus for 1 hr. at 5-10 lb. per sq. in. pressure. For "print" style astrakhan, dyeing and setting are combined, and for a black and white effect the warp is blued before curling and chromed after curling. W.

#### (D)—YARNS AND CORDS

**Nylon Rope: Uses.** *British Plastics*, 1944, 16, 153. A nylon rope of about half an inch diameter can lift a load of 3 tons and is about twice as strong as a manila rope of the same thickness. Its weight is half to two-thirds that of a manila rope of equal diameter. The elasticity of a rubber band or a steel spring expresses itself in a quick snap. Nylon rope, in contrast, has a slow, gentle "bounce." Under stress of a sudden pull, nylon rope stretches rapidly but recovers slowly, the action of the perfect shock absorber. This shock-absorbing characteristic provides one of the advantages of the use of nylon mailbag loops and winch lines for the picking up of air-mail by travelling planes. Nylon ropes are also used for gliders and as climbing ropes for mountain troops. C.

**Wool Crêpe Yarns: Manufacture.** S. Kershaw. *Text. World*, 1944, 94, No. 2, 111, 120. Methods are described for spinning and twisting singles crêpe yarn, and also Z on S and Z on Z twist yarns, and examples given of the count and twist allowances to be made for yarn contraction. Precautions necessary to prevent snarls are suggested. W.

## PATENTS

**Spinning Frame Clearer Roller.** Dominion Textile Co. Ltd. (Montreal). B.P. 560,381 of 24/9/1942:3/4/1944 (Conv. 1/10/1941). A clearer roller for spinning frames and like textile machines comprises a hollow cylindrical form, a cloth cover mounted on the form and secured to the surface thereof with its free ends in-turned over the ends of the form, and a plug inserted in one or each end of the form to engage one or each of the free ends. The plug may be mushroom shaped with the stem portion extending within the form. The roller may comprise two or more hollow cylindrical forms connected and spaced apart by a plug or plugs carrying a collar or collars of a smooth wear-resistant material serving as friction-free journals by which the roller may rotate against stationary bearings. The cloth cover may be a braided tube. C.

**Rayon Staple: Spinning on Flax Spinning Frame.** J. Wilson and W. Gibson (Belfast). B.P. 560,635 of 7/8/1942:13/4/1944. In a wet spinning frame of the type used for flax means are provided to enable the drawing and dry spinning of rove of which the staple length is greater than that of the normal maximum reach of the frame, e.g. "Fibro" having a staple length of about 4 inches. The means comprise a guide offset from the path of the normal straight reach so that the rove passing from the retaining to the drawing rollers and over the guide means consists of two stretches angularly related to the normal path and of greater total length than said path and of which the stretch between the guide and the nip of the drawing rollers is sufficiently greater than the length of the normal maximum reach to allow the necessary drawing action. The guide may comprise a guide bar so offset from the normal reach that the rove passing around the bar is subjected to a change of direction of the order of 180° and a consequent frictional drag. C.

**Carding Engine Ventilation and Dust Removal Apparatus.** S. Holt. B.P. 560,969 of 9/12/1942:28/4/1944. Ventilation and dust removal apparatus for cotton carding engines consists of a fixed self-contained unit supported above the cylinder, doffer and licker-in, the unit comprising a motor-driven fan having a vertical axis, a dust filter or separator on the fan outlet which returns the filtered air to the cardroom, and a hood on the fan inlet located over the machine so as to confine fluff or dust given off by the machine to an area to which suction is applied. The portion of the hood which extends over the doffer may telescope within the centre portion of the hood so as to give access to the doffer when the stripping of the latter of the hard nebs which become embedded therein is to be performed, the telescoping part being replaced in its extended position during the actual stripping operation. Similarly, the portion of the hood which extends over the licker-in may be hinged to the remainder. Side flaps, which may be made of sheet metal, may be suspended from the hood by hooks. C.

**Ring Traveller.** P. C. Wentworth. U.S.P. 2,333,755. The traveller comprises a bow and terminal horns that are split centrally and opened out so that they provide a wider bearing surface on the ring. It is claimed that the traveller is much less likely than usual to swivel and ride the ring flange. C.

**Wet Twisting Frame.** H. V. Lang (Charlotte, N.C.). U.S.P. 2,334,420. Yarn from supply packages passes through tension rollers, then over a roller (A) rotating at an adjustable speed in a trough containing a treating solution, and is twisted by means of a ring and traveller combination (B). Between (A) and (B) the yarn rubs along a curved trough which can be swung out of the way for doffing. C.

**Knub Yarn Production Apparatus.** Alexander Cavedon (Woonsocket, R.I.). U.S.P. 2,334,542. Apparatus for making knub yarns comprises means for conveying a web of carded fibre to a condenser, rollers controlled by a ratcheting device for feeding a predetermined length of knub material to a fixed and a movable cutting blade, and means for depositing the cut knub material uniformly across the card web. C.

## 3—CONVERSION OF YARNS INTO FABRICS

## (B)—SIZING

**Rayon and Cotton Warp: Sizing.** O. Pennenkamp. *Spinner u. Weber*, 1943, 61, No. 4, 2-6 (through *Chem. Zentr.*, 1943, i, 2367 and *Chem. Abstr.*, 1944, 38, 1119<sup>b</sup>). The requirements of a good size, hank and warp sizes, advantages of

the latter, and sizing agents for slasher sizing are discussed and numerous sizes for general and special purposes, particularly for staple fibre, are listed. C.

**"Cellufix" Paste: Uses.** *Nature*, 1944, 153, 616. The Swedish Cellulose Co. has recently put on the market a wood-pulp product named "Cellufix," the manufacture of which requires the use of alkali, chlorine and alcohol. It is odourless and tasteless, soluble in water, and a 3 per cent. solution has the consistency of butter. At present it is mainly used as wall-paper paste, as putty, for part of white-wash, and in textile mills as size and for other purposes. A specially purified quality of Cellufix, called "Cellugel," is used in the food and chemical industries to give bulk to certain products and is also a substitute for glycerin. C.

**Infra-red Drying Lamps: Application in Sizing.** Ware Shoals Manufacturing Co. (S. Carolina). *Textile World*, 1944, 94, No. 3, 83. An illustrated account is given of an application of infra-red lamps by which a 40 per cent. increase of production was secured at the tape frame. An asbestos hood, 7 ft. long, 57 ins. wide and 16 ins. deep, with protective flaps hinged to the sides, is suspended over the warp sheet between the size box and the usual drying cylinders, which operate as usual. The hood is wired for 120 Westinghouse infra-red lamps (250-watt, 110-volt). A sheet of metal below the warp is suggested as a reflector to dry the under surface. C.

**Tape Frame: Speed Calculation.** H. D. Tendulkar and D. F. Kapadia. *Indian Textile J.*, 1944, 54, 187-189. The authors analyse the physical factors that govern the output of the tape frame, and argue that the number of ends in the warp sheet is without influence on the speed of the machine, but that the air gap between the warp and the surface of the drying cylinders is responsible for most of the loss of thermal efficiency. They derive the following equation connecting the speed,  $S$  (yards per second), count of yarn,  $n$ , percentage of dry size added,  $s$ , and percentage of free water that has to be evaporated,  $p$ :  $S = 31.8(n/s) \cdot \{ (100-p)/p \}^{1/2} \cdot 1/(29+0.8n)$ . A table shows values of  $S$  calculated for  $n$  20-120,  $s$  50-10 and  $p$  30-88; they range from 42.6 to 24.9 yards per minute and agree with what is said to be "general mill practice." C.

**Cotton Mill Waste: Reduction and Utilization (for Tape Frame Blankets).** See Section 2(B), above.

#### (C)—WEAVING

**"Bracewell" Automatic Loom.** Messrs. Greaves Cotton & Co. Ltd. (Agents; Bombay). *Indian Textile J.*, 1944, 54, 194-195. An illustrated description is given of a loom, now being manufactured in India, that combines a circular shuttle box for four shuttles with a hammer pirn-changing motion for replenishing an exhausted shuttle from a magazine. When the weft in the operative shuttle is spent, a weft-feeler motion or weft-fork causes a quarter rotation of the shuttle box, thus bringing a full shuttle into play. This is then picked to the opposite side of the loom and when the sley is next at front centre the transfer hammer brings a fresh bobbin from the magazine into the exhausted shuttle and ejects the empty bobbin. The mechanism can be applied to ordinary over-pick looms after minor alterations. C.

**Loom Picking Motion: Adjustment.** *Cotton (U.S.)*, 1944, 108, No. 2, 137-139. Practical hints are given on the adjustment of the picking motion, with special reference to the relation between picking and (1) shedding, (2) the fell of the cloth and (3) "banging off." C.

**Rayon Loom: Maintenance.** A. C. Wayman. *Textile World*, 1944, 94, No. 2, 116-117. Hints are given on the routine to follow when cleaning a loom, replacing worn parts, oiling, and starting again. A record chart is reproduced for filling in by the responsible workers when "warps are out." C.

**Damaged Cloth: Tracing Responsibility.** *Textile Weekly*, 1944, 33, 794-8, 836-840. Practical hints are given on the causes of various types of damage in cloth, and the responsibility for them of the weaver and the overlooker. C.

**Rayon Fabric with Holes and Floats: Correction in Weaving.** H. E. Wenrich. *Rayon Textile Monthly*, 1943, 24, 644-6; 1944, 25, 26-27, 82, 131-132, 179-180. Practical advice is given on the reduction of floats and holes in weav-

ing rayon, including the ripping out and repair of floats, effective admonition of the weaver, and the influence of bad sizing, rough shuttles, timing the shedding and heald lifting, knots, the height of the shed, timing the pick, loose yarn on the beam, breaking of selvage ends, and the covering of the take-up roller. C.

**Weft Bars in Rayon Fabrics: Prevention.** *Silk and Rayon*, 1944, 18, 430-432. Practical hints are given on the avoidance of weft bars in rayon crêpes, taffetas, etc., chiefly those due to a faulty ratchet wheel in the take-up motion and to a wrongly set beam motion. C.

**Automatic Looms: Developments.** *Wool Rec.*, 1944, 65, 591-592. The extent to which textile machinery was imported from the Continent before the war is discussed, with particular reference to developments in automatic looms. Automatic weaving and winding machinery is now being given some attention in this country. W.

**Worsted and Mohair Mixture Cloths: Weaving.** "Practical Overlooker." *Text. Rec.*, 1944, 61, No. 732, 48-50. Practical suggestions are made for overcoming difficulties in the weaving of plain cloth with worsted warp and mohair weft. W.

#### (G)—FABRICS

**Rayon Shirting: Specification and Testing.** P. Lebrun. *Textile World*, 1944, 94, No. 2, 120. American Navy Specification No. 55-B-18a calls for a shirting for blouses for the women's services, with the following minimum particulars: 112 ends per inch of continuous-filament viscose yarn, 72 picks per inch of spun viscose, 3.2 oz. per sq. yd., warp and weft breaking loads 50 lb., shrinkage in wash 2 per cent., either way. The material is white or dyed navy blue and if dyed should be fast to washing at 160° F. with soap and soda ash, fast in a Fadeometer exposure of 40 hours. Hints on finishing the cloth are given; impregnation with 2-3 per cent. of a melamine resin is recommended. C.

**Shirley Institute Water-repellent Cotton Fabric.** *Textile World*, 1944, 94, No. 3, 85. A hint is given of the interest aroused in the United States by the B.C.I.R.A. development of water-repellent canvas and uniform fabrics. Some particulars of their construction are reproduced from the British patent specification No. 549,974. A similar experimental cloth produced in the United States is an Oxford fabric, 136 × 52, 60/3s in both warp and weft, the twist factor of the singles in the warp being 2.75. C.

**Terry Towel Cloth: Costing.** O. Pomfret. *Textile Manufacturer*, 1944, 70, 150-3, 157. Methods of costing in the terry trade are discussed and an example is worked out by three methods that differ in detail. C.

**Weaving Calculation Tables.** E. Whitworth. *Textile World*, 1944, 94, No. 3, 84-85. The following examples are given of tables to facilitate weaving calculations: (1) Production in thousands of picks by a loom running at 132 p.p.m. for 40, 32, 24, 16, 8 hours or 1 hour at various efficiencies down to 76 per cent.; (2) Costs per yard of cloths from 110 to 56 picks per inch at 1, 2, 3 . . . 9 cents per 1,000 picks. C.

**Utility Fabrics: Conception, Birth and Development.** Sir Thomas Barlow. *J. Soc. Dyers & Col.*, 1944, 60, 53-55. W.

**Felt Hat Making.** F. J. Knight. *Canadian Text. J.*, 1944, 61, No. 4, 42, 44, No. 5, 37, 39. A description of the manufacture of fur and wool felt hats, from the selection and blending of the raw material to the finishing operations. W.

**Military Fabrics: Serge.** *Text. World*, 1943, 93, No. 12, 80-83. An abstract is given of U.S. Army Specification No. 8-94 A. for 18-oz. serge, together with detailed suggestions for manufacturing and finishing procedure. W.

#### PATENTS

**Cross-wound Cop Winding Machine.** Maschinenfabrik Schweiter A.-G. (Switzerland). B.P. 560,319 of 1/7/1942: 30/3/1944 (Conv. 1/7/1941). A cross-wound cop winding machine for winding conical cops with conical ends on conical bobbins includes a slider which is reciprocated with a constant stroke by means of a throw rod and carries an oscillatable thread guide arm operatively connected to a pivoted slide link in such a manner that the degree of oscillation

of the thread guide is controlled by the inclination of the slide link relative to the line of movement of the slider. These parts are oscillatably mounted as a whole about an axis parallel to the line of movement of the slider so that with an increase in diameter of the cop being wound the said parts are caused to swing as a whole about the axis by reason of the engagement of the thread guide with the cop in such a manner that with an empty bobbin the slide link is so positioned that the maximum movement of the thread guide results from the combined oscillation of the thread guide arm and the motion of the slider whilst with increasing diameter of the cop the position of the slide link is varied to cause the movement of the thread guide arm to be gradually reduced to a minimum. The axis of the bobbin to be wound is inclined to the axis of the throw rod so that the line traced by the thread guide on the cop runs parallel to the taper of the conical bobbin on which the cop is being wound. Preferably the slide link is pivotally mounted on an axis at right angles to the line of movement of the slider. C.

**Double-pick Loom.** H. Seal & Co. Ltd. and J. Webster. B.P. 560,330 of 28/9/1942:30/3/1944. A loom of the type having a batten or sley movable to-and-fro in beating up is provided with means for making two picks for each revolution of the main shaft, for shedding between successive picks, and for beating up after every second pick. Conveniently, the shuttle is driven by a two-lobed tappet or cam on the half-speed shaft. The sheds are made by a suitable arrangement of healds operated from a dobby or tappets or both. C.

**Nylon Yarn: Sizing and Twisting.** E. I. Du Pont de Nemours & Co. B.P. 560,538 of 5/10/1942:7/4/1944 (Conv. 4/10/1941). A method of producing a highly-twisted and sized nylon yarn in a continuous operation, comprises sizing and winding a nylon yarn having less than five turns per inch twist, drying the sized yarn during the continuous operation at a temperature up to 50° C. at a sufficiently high rate so that the completely wound package has a moisture regain of not more than 12 per cent., and subsequently imparting a twist in excess of 15 turns per inch to the yarn. Examples are given of the sizing of 30-denier, 10-filament yarn, using a basic size composition containing partially hydrolysed polyvinyl acetate, boric acid and polyethylene glycol. C.

**Tapered Package Winding Apparatus.** Courtaulds Ltd. and C. H. Hampson. B.P. 560,637 and 560,657 of 21/8/1942:13/4/1944. (1) Apparatus for winding thread packages tapered at each end comprises a roller mounted on a thread guide arm which is fixed on an axle and connected by an intermediate bracket to a short rod passing through a slot in a lever that oscillates about a fixed fulcrum, the whole being so arranged that as the distance between the thread guide and the roller increases, the short rod moves in the slotted lever towards the fulcrum, and so causes the traverse given by the slotted lever to be shortened. (2) Apparatus for winding thread packages tapered at each end comprises a rotating roller, a thread guide carried at one end of an arm to the other end of which is fastened a rod that passes through a slot in a lever pivoted to a traverse rail by which it is oscillated about a fulcrum, whereby the arm is reciprocated along an axis parallel with the roller and swings about the axis as the package fills, thereby moving the rod in the slot nearer to the fulcrum of the lever so that the traverse of the thread guide is shortened. Both inventions may be applied to machines in which the thread is wound on a roller forming a package which is rotated by contact with a driven drum, or to winding apparatus in which the thread is collected directly on a roller through the centre of which passes the driving shaft. C.

**Hank Reel.** W. Gibson. B.P. 560,863 of 20/3/1942:25/4/1944. A reel or like machine for winding yarn into a hank consisting of close side by side windings and which comprises or is adapted to receive a swift or equivalent rotary member for the yarn, is provided with yarn guide and drag means to prevent whipping of the yarns passing to the swift so that they are closely and accurately laid side by side on the swift, and means whereby the windings are automatically sub-divided into cuts as they are wound. The dividing means comprise cross-members each having a sharp dividing edge presented outwardly and spaced along the swift to constitute notches or recesses of such width as to receive the predetermined number of windings constituting a cut, each notch having a yarn-supporting surface offset from the corresponding surface in the

adjacent notches to cause adjacent cuts or groups of windings to lie in different planes or be offset to facilitate leasing or tying them into hanks. Preferably the yarn guide and drag means comprise yarn guides offset in the direction of traverse from the yarn bobbins so that the yarns bend round the guide means in passing from the bobbins to the swift and a drag arrangement for each bobbin. C.

**Hank Winding Reel.** W. Gibson. B.P.560,890 of 20/3/1942:25/4/1944. A reel or like machine for winding yarn into hanks, which comprise a number of cuts preferably adapted to be leased or tied together in one operation at the conclusion of the winding of the hank, by a continuous relative traverse between a swift, which preferably has means for dividing the yarn into cuts as they are wound, and yarn-guiding means, comprises traversing means driven from the swift-driving shaft and including a rotary traverse wheel which makes several complete revolutions in the course of winding a hank and separable toothed members driven by the traverse wheel and of which the tooth pitch or spacing is such as to correspond to a traverse movement equivalent to a substantial number of windings, a clutch between the swift-driving shaft and a primary driving shaft, clutch-operating mechanism, manual control means for the mechanism and automatic stop means for controlling the mechanism including an element held inoperative by a part traversing with the yarn-guiding means until the traverse wheel has commenced its last revolution and further held inoperative by a support rotating with the traverse wheel only until the latter has completed its last revolution when the element is freed to cause disengagement of the clutch when the hank has exactly been completed. Preferably the clutch-operating mechanism comprises pivotally related members adapted respectively to be on opposite sides of a dead centre position when the clutch is engaged or disengaged and spring means adapted automatically to hold the members in either of the positions, and preferably the manual means comprise a hand rod extending along above the supply bobbins and yarn guiding means. C.

**Loom Beat-up Mechanism.** Brough, Nicholson & Hall Ltd. and H. Pegg. B.P. 560,993 of 26/10/1942:1/5/1944. A loom is provided with a reed that includes an upper section disposed vertically in the warp shed in its retracted position, a lower vertical beat-up section located considerably in advance of the upper section and disposed below the warp shed in proximity to the fell of the cloth, an intermediate section extending between and connecting the upper and beat-up sections, and means to reciprocate the reed in a movement having vertical and horizontal components so that the reed is lifted bodily through the warp shed to bring the lower beat-up section into alignment with the warp shed and then undergoes a limited horizontal beat-up movement. The reed may be mounted to pivot about an axis adjacent the beat-up section and the upper and beat-up sections may be disposed at an angle to one another such that the upper section lies on an arc or chord of a circle described about the axis, and interconnected by an intermediate section extending parallel to the general direction of the warp shed in the retracted position of the reed, means being provided to oscillate the reed angularly from a position wherein the upper reed section lies in a plane at right angles to the general direction of the warp to a beat-up position in which the beat-up section is disposed vertically. The reed wires in the intermediate forwardly projecting section are preferably arranged so that alternate wires are located in different planes thus providing a greater interval between adjacent wires. This increased spacing provides improved facilities for the passage of yarn defects and in conjunction with the reduced beat-up movement results in a considerable reduction in the friction or abrasion between the reed and the warp threads. Means may be provided to ensure the weft thread being carried forward to a position in front of the beat-up section of the reed before the reed undergoes its vertical movement. C.

**Straight-bar Knitting Machine Thread Carrier Mechanism.** G. Blackburn & Sons Ltd. and H. W. and E. Start. B.P.561,082 and 561,103 of 29/8/1942:4/5/1944. (1) In thread carrier mechanism, particularly plating mechanism which will permit of plated or spliced work being produced with the machine running at the same speed as that used for the production of ordinary work, each of one or more of the thread carriers associated with each knitting head in the machine is connected to a member slidably

mounted on a reciprocating bar and positively driven thereby between end stops. The driving connection between the reciprocating bar and the driven member is arranged so that the driving connection is made when the thread carrier is disposed a predetermined distance in front of the slur cock and broken when the member engages with or is close to the end stops. Locking mechanism is provided to prevent rebound of the member when it engages with the end stops. (2) In thread carrier driving mechanism, particularly plating mechanism which will permit of plated or spliced work being produced with the machine running at a greater speed than that normally used for the production of this class of work, each of one or more of the thread carrier bars is connected to an associated member slidably mounted on a bar and positively reciprocated between end stops by a reciprocating bar. Each member is preferably mounted on the reciprocating bar and the driving connection between the reciprocating bar and the driven member is arranged so that it is made when the thread carriers are a predetermined distance in front of the slur cocks and broken when the members engage with or are close to their end stops. Locking mechanism is preferably provided to prevent rebound of a member when it engages with its end stops. C.

**Stocking with Separately-knitted Foot and Leg.** K. Allsop Ltd. and R. L. Carter. B.P.561,114 of 2/11/1942:5/5/1944. A stocking comprises a separately-knitted foot and leg, and a turnover top at the ankle, which three parts are permanently united by linking or seaming to form a single garment giving the appearance in wear of an ankle sock worn over a stocking. If the foot becomes worn or the leg is laddered it is possible to replace the damaged part of the stocking. The foot and the turnover top may be made in one and the leg, made without a foot, attached thereto or the three parts may be made separately. The turnover top is preferably ribbed. C.

**Knitting Machine Sinkers.** Scott and Williams Inc. U.S.P.2,333,667. Each sinker of a knitting machine with independently movable latch needles and sinkers comprises a ledge for holding yarn during the drawing of loops, a hook behind the ledge to provide a throat for holding yarn during the movements that free the latches of loops, and a butt behind the hook for the cam actuation of the sinker. C.

**Triethanolamine Ester Cellulose Acetate Yarn Dressing Agent.** Eastman Kodak Co. U.S.P.2,333,770. A lubricating and softening agent for cellulose acetate yarn contains as essential ingredient triethanolamine mono-acetate di-propionate. C.

**Multiple-box Loom Wrong Weft Excluder.** A. S. Dawkins and J. A. McFalls (Rockingham, N.C.). U.S.P.2,333,846. The claim is for a device to prevent weft from idle shuttles from being jerked into the shed. The cams that actuate the shuttle boxes also carry lifting bars and wires to lift the idle wefts out of the way. C.

**Elastic Selvedge for Knitted Fabric: Construction.** Hemphill Co. U.S.P. 2,333,870. Elastic yarn is knitted into alternate loops of the fabric under such tension that on release it will bind the stitches to form a non-ravelling edge. C.

**Elastic Stocking Top: Construction.** Hemphill Co. U.S.P.2,333,882. An elastic yarn is fed to alternate needles of a series at one feed of a plain multi-feed machine, then a plain yarn is immediately fed at a separate station, this plain yarn is knitted on all the needles so that the elastic yarn is cast off to be held by sinker wales of an initial course, then the elastic yarn is fed to the hooks of all the needles, but knitted on alternate needles only and tucked on the others, and plain yarn is finally knitted through the knitted and tucked elastic stitches. C.

**Knitting Machine Fabric Take-up Mechanism.** Hemphill Co. U.S.P.2,333,897. The rollers of the take-up mechanism are mounted on spindles so that they may move in parallel or angular relationship to and from each other through an extent sufficient to separate them entirely. C.

**Pick-and-Pick Loom Weft-replenishing Mechanism.** Crompton & Knowles Loom Works. U.S.P.2,333,904. A loom operating with a number of shuttles for plain weft and one for distinctive weft, reserve wefts being supplied from a magazine, has a pair of shuttle boxes at the magazine end of the sley and a gang

of three shuttle boxes at the opposite end, one to serve as the home box for the distinctive weft. The boxes operate normally in 4-pick cycles, each for two successive picks, but means are provided to interrupt the normal cycle when the distinctive weft shuttle is to operate. Weft replenishment occurs while the boxes are inactive. C.

**Warp Knitting Machine Patterning Mechanism.** Rudolph Bassist and others. U.S.P.2,334,058. The machine has a pattern-actuated cam shaft for operating the needles and yarn guide bar and for imposing on the warp beam a fluctuating component of movement corresponding with the fluctuating demands for yarn by the intermittently-moving guide bar. C.

**Knitting Machine Adjustable Draw Cam.** George W. Borg Corporation, U.S.P.2,334,353. The claim is for latch means for the alternative positioning of the draw cam for loose stitch or tight stitch control. C.

**Shuttle Spindle.** Draper Corporation. U.S.P.2,334,675. The claim is for a pivoted spindle and means, comprising a spring, a cam-surfaced abutment and a stop, for holding the spindle in its working position in the shuttle. C.

## 4—CHEMICAL AND FINISHING PROCESSES

### (A)—PREPARATORY PROCESSES

**Wetting Agents and Detergents: Volumetric Determination.** J. M. Preston. *Chemistry and Industry*, 1944, 176-177. In a method of volumetric analysis which is applicable to wetting agents and detergents, an anion-active solution is generally titrated with a cation-active solution, but the method is not limited to the case where both ions are surface active. As the titration proceeds, the surface active ions mutually precipitate one another and the end point is shown by a sharply-defined maximum surface tension. During the titration the surface tension is followed by observing the pressure that is required to force a slow stream of air bubbles at a constant rate through the solution in the titration vessel. With some pairs of cation- and anion-active substances the change of pressure at the end point is as great as 25 per cent. of the total pressure, which includes the hydrostatic pressure. The pressure is measured by an inclined tube manometer with a magnification of 20. Working in suitable concentrations, changes of the manometer of 1 to 4 cm. are observed at the end point for the addition of 0.1 c.c. to a total volume of about 40 c.c. Solutions of surface-active substances, such as branched and straight chain alkyl sulphates containing about  $C_{18}$ , oleic acid and sulphated castor oil soaps, and cetyl pyridinium and cetyl trimethyl ammonium bromides, give satisfactory results at concentrations of about M/1000. Comparison of the results of analyses by the new method with those obtained by other methods are satisfactory. C.

### (B)—BOILING, SCOURING, DEGUMMING AND WASHING

**Rayon Crêpes and Staple Fibre Fabrics: Processing.** J. Chadwick & Co. Ltd. *J. Textile Inst.*, 1944, 35, P33-40. C.

**Scouring and Milling: Treatment of Felts and Flannels.** D. R. H. Williams. *Wool Rec.*, 1944, 65, 628, 631, 633. The characteristics of the Williams-Peace combined scouring and milling machine, particularly the movable mouthpiece, have proved especially valuable in milling airplane tank felts, R.A.F. woollen weft serge and Morley flannel. Particulars are given of the milling of these three types of fabrics. W.

### (E)—DRYING AND CONDITIONING

**Porous Materials: Drying; Diffusion Phenomena.** E. F. M. van der Held. *Gesundh.-Ing.*, 1941, 64, 211-216 (through *Chem. Zentr.*, 1941, ii, 382 and *Chem. Abstr.*, 1944, 38, 1159<sup>7</sup>). A differential equation is derived for diffusion at constant and variable temperatures in a gas, and applied for the case of evaporation from a surface. The analogy to conduction of heat is used. For diffusion in porous materials a modified diffusion factor is assumed, derived from that for the diffusion of two gases into one another by multiplication with the pore surface per unit area, and division by the mean length of the canals between two parallel surfaces at a distance of 1 m. C.

## (G)—BLEACHING

**"Blankophor" White Fluorescing Substances: Application to Bleached Materials.** R. Michel. *Färber u. Chemischreiniger*, 1942, 110-111 (through *Chem. Zentr.*, 1943, i, 2550 and *Chem. Abstr.*, 1944, 38, 1119<sup>5</sup>). The customary bluing can be replaced by optical methods, especially the application of white fluorescing substances, the Blankophors (I.G. Farbenindustrie). Blankophor B is suitable for bleached cotton, semi-bleached linen and slightly bleached or unbleached staple fibre and rayon; it gives a bluish white tint. Blankophor R gives a violet-white tint. Blankophor WT is suitable for animal fibres. Recipes and applications are discussed. C.

**Sulphite Pulp: Bleaching; Effect of pH.** I. S. Khutorschikov. *Bumazhnaya Prom.*, 1940, No. 11, 24-28 (through *Khim. Referat. Zhur.*, 1941, No. 7-8, 118 and *Chem. Abstr.*, 1944, 38, 1109<sup>6</sup>). The content of  $\alpha$ -cellulose of sulphite pulp and the viscosity in cuprammonium are lowest when the pH of the bleaching solution is 6-7. The amount of chlorine used is smallest at pH 9.5. The time required for bleaching is shortest in neutral media. This is attributed to the greater stability of chlorolignin in an acid medium. C.

**Mechanical Pulp: Sodium Peroxide Bleaching.** J. S. Reichart. *Paper Trade J.*, 1944, 118, TAPPI, 89-96. The development of sodium peroxide bleaching of mechanical pulps is reviewed and details are given of the procedure, equipment, reagents, control tests, yields and costs. The process consists essentially of three steps: (1) rapid and thorough mixing of the sodium peroxide bleaching solution with the pulp in controlled proportions, (2) storing the treated pulp long enough to permit the bleaching to go to completion, and (3) mixing the bleached pulp with a neutralising and reducing agent. The effects of a number of variables, such as the type of wood, ageing of the pulp, quality of water, and bleaching conditions, are discussed. The results of preliminary work have shown that substantial increases in pulp brightness are obtainable with practically no weight loss at a cost well within economic limits. The bleached pulp retains most of the desirable characteristics of unbleached groundwood and some valuable new properties are developed in the bleaching treatment. The bleached pulp can be used in the manufacture of a wide range of papers. C.

**Peroxide Bleach Liquors; Action and Control of Metal Catalysts in —.** J. S. Reichert, D. J. Campbell and R. T. Mills. *Paper Trade J.*, 1944, 118, TAPPI, 125-128. Tests with solutions of hydrogen peroxide and sodium peroxide have shown that copper, iron and manganese accelerate peroxide decomposition; the effect is catalytic and varies with the pH of the peroxide solution. De-activation of these metal catalysts can be accomplished by the addition of agents that inhibit peroxide decomposition within pH ranges peculiar to each stabilizer. Stabilization over a wide pH range can be produced by the use of a mixture of sodium silicate and magnesium sulphate. C.

## (I)—DYEING

**Dyed and Printed Cotton Fabrics: Fastness to Washing.** See Section 5C.

**Acid and Basic Dye Compounds: Application.** *Silk and Rayon*, 1944, 18, 428, 443. The practice of "topping" direct cotton dyeings or acid wool dyeings with basic dyes suggests the possibility of applying compounds of direct or acid dyes and basic dyes, preformed by the dye maker. One scheme is to search for compounds that are soluble in organic solvents, though not in water, and reference is made to B.P.555,410 (Geigy & Co.) as an example. The basic dye may be replaced in part by organic bases. C.

**Autazol Chrome Dyes: Application.** C. Blau, Jr. *Färber u. Chemischreiniger*, 1941, 22-23 (through *Chem. Zentr.*, 1941, ii, 116 and *Chem. Abstr.*, 1944, 38, 1367<sup>9</sup>). Autazol chrome dyes dye wool, cotton and particularly staple fibre fast and uniformly in a neutral or faintly acid ammonium sulphate bath. Commercial products are Autazol Chrome Black R, BA and Autazol Chrome Navy Blue BRA. The dyeing is followed by diazotisation with nitrite and acid, rinsing with ammonia and after-treating with a chromium salt. The R grade needs to be after-treated only with Autazol Chrome Salt R. The addition of Leonil O, Igepon or Igepal to the bath increases the absorptive power of the woollen fibre. Colour shading can be effected with Sirius or diazo dyes or with Chrome

Oxan dyes, etc. Acetate rayon is not dyed; it must be treated with Cellitazol STN conc., or AZN and developer ONL. C.

**Cottonin: Dyeing.** F. Gund. *Kleppzig's Textil Z.*, 1943, 46, 143-147 (through *Chem. Zentr.*, 1943, ii, 276 and *Chem. Abstr.*, 1944, 38, 1369<sup>8</sup>). The manufacture and properties of cottonin are discussed. Since it is used chiefly for working clothing, army requirements, knapsack fabrics, etc., it is dyed chiefly with indanthrene, hydrone and sulphur dyes. With indanthrene dyes, the application of the temperature step process is recommended, together with dyes of the IW and IK series. For the piece goods dyeing of bread bag and soldiers' knapsack fabrics, certain dyes are needed which dye "dead" fabrics well, e.g. Indanthrene Khaki GG, Olive R, Yellow 3R and 3RT, and Brown 3GT. The pigment slop-padding process is the best dyeing method. In dyeing twills consisting of staple fibre 60 per cent. and cottonin 40 per cent. with Hydron Blue, cottonized hemp produced dyeings of poor washing fastness, whilst cottonized flax gave better results. The cause is the presence of shives in the cottonized hemp. C.

**Fine and Coarse Rayons: Dye Concentrations for Same Shade; Determination with a Nomogram.** F. Fothergill. *J. Soc. Dyers & Col.*, 1944, 60, 93-95. The reason why a fine-filament yarn requires more dye than a coarse filament yarn to make it appear the same shade is explained and it is shown that  $C_2/C_1 = \sqrt{D_1/D_2}$ , where  $C_1$  and  $C_2$  are the dye concentrations and  $D_1$  and  $D_2$  the filament deniers. A nomogram for facilitating calculations based on this relation is presented and its use is explained and illustrated by examples. The accuracy of the results is discussed. C.

**Glycerin: Textile Applications.** Georgia Leffingwell. *Textile Research*, 1944, 14, 69-73. A review of recent developments in the use of glycerin in dyeing and printing, in textile oils and lubricants, and in the production of alkyd resins for the coating and treatment of fabrics, for use in dyeing and printing, and for the production of protective coverings for supports, e.g. yarn supports used in package dyeing. C.

**Spun Rayon Fabrics: Dyeing.** K. Rickert. *Deut. Färber-Ztg.*, 1943, 79, 75-77 (through *Chem. Zentr.*, 1943, i, 2735 and *Chem. Abstr.*, 1944, 38, 1369<sup>5</sup>). Causes of streaky dyeing of spun rayon fabrics are discussed. Decreased dye absorption can be caused by increased longitudinal orientation and increased density of the micelles. Viscose staple fibre contains a distinct fibre coat around a soft kernel; this is absent in Cu, Lanusa and Schwarza staple fibre. Dyeing experiments with 15 staple rayons, American cotton and German wool AB with Sirius Red 4B, Semiwool Fast Gray G and Sirius Light Green BB are reported. Delustred fibres consume more dye than non-delustred fibres; non-delustred staple fibre rendered hydrophobe behaves similarly to the ordinary delustred types. C.

**Winch Dyeing Machines and Washers: Application.** *Textile Weekly*, 1944, 33, 721-7, 830-4. A general account is given of the various types of winch dyeing and washing machines in common use, the choice of timber for winches, the efficient running of the machines, and variations imposed by the textile material under treatment. C.

**Cellulose Fibres: Dye Absorption.** D. Krüger. *Kleppzig's Textil Z.*, 1943, 46, 179-182 (through *Chem. Zentr.*, 1943, i, 2735 and *Chem. Abstr.*, 1944, 38, 1370<sup>3</sup>). The absorption of substantive dyes and the inner surface of cellulose materials, dyeing with base exchange and the dyeing of glass fibres are discussed. In the dyeing of cellulose fibres with substantive or with basic dyes, there are superimposed different reactions, due partly to differences in the inner structure and chemical composition of the fibre and partly to the properties of the dye molecule, of such a nature that it is impossible to determine accurately the inner surface of the fibre or the active groups of the cellulose molecule by this method. C.

**Dyes: Polymorphism.** I. Riskin. *J. Applied Chem. (U.S.S.R.)*, 1943, 16, 201-205 (through *Chem. Abstr.*, 1944, 38, 1367<sup>9</sup>). The dyes Red B and Hansa Yellow 3R (I.G. Farbenindustrie) can form two crystalline modifications, depending upon the solvents used. The form obtained from toluene is believed to be the principal form, whilst the second form, obtainable from pyridine solution, is believed to be secondary. The crystals have lighter colour in the second modification. C.

**Camouflage Textiles: Infra-red Reflectance.** E. I. Stearns. *Amer. Dyes. Rept.*, 1944, 33, 131-136. The importance of infra-red reflectance is discussed and it is pointed out that to offer good concealment a camouflage sample must match the surrounding natural colours not only visually, but also by infra-red photography. By a study of examples it is shown how the degree of detectability of any camouflage under visual observation or by the conventional infra-red photographs can be deduced. Camouflage specification tests, dyeing problems, photographic tests using Eastman infra-red film and Wratten light filters, and the interpretation of spectrophotometric data by the ten selected ordinate method are discussed. C.

**Dyeing Hair.** *Dyer*, 1944, 91, 13-14, 55-57, 93-94. Methods are given for dyeing mohair, alpaca, camel hair, horsehair, cow hair (including needle felt), goat hair and human hair. Methods are also recommended for stripping mohair and human hair. W.

#### (K)—FINISHING

**Spun Rayon Fabrics: Finishing with Formaldehyde and Resins.** W. Gutmann. *Kleppzig's Textil-Z.*, 1943, 46, 49-51 (through *Chem. Zentr.*, 1943, i, 2464 and *Chem. Abstr.*, 1944, 38, 1120<sup>1</sup>). The high swelling power of cellulose can be decreased by blocking the hydroxyl groups with formaldehyde or by introducing urea-formaldehyde resins into the fibre. The formation of dimethylolurea (I.G. Farbenindustrie's Kaurit KF) from urea and formaldehyde is described. The polymerisation of Kaurit KF in the presence of acid catalysts takes place best at temperatures of 115° or higher. The principal advantage of the use of Kaurit is improved creaseproofness, whilst treatment with formaldehyde improves washing resistance. The proper management of formaldehyde treatment is described. An organic formaldehyde carrier, e.g. Kaurit WF 110, makes it possible to improve the wet strength and to lower the swelling power. The technique of Kaurit application is discussed and the fixation of the following finishing agents with Kaurit WF is described: starch, Tylose TWA, Appretan EM, Na, WL, D, Persistol KF, Soromin BS, FL, SG, FFAN, AM and Ramasit S. C.

**Spun Rayon Fabrics: Swelling-proof Finish.** F. Haberl. *Deut. Textilwirt.*, 1943, 10, No. 3-4, 28-29 (through *Chem. Zentr.*, 1943, i, 2651 and *Chem. Zentr.*, 1944, 38, 1120<sup>4</sup>). The occurrence and the effect of swelling, treatment with urea resin and formaldehyde, and the changes caused by this treatment are discussed. The diminution in swelling of the finished fabric should not exceed 40 per cent. of the original value, the decrease in elongation in the dry state should not be more than 25 per cent. of that of the untreated goods and the residual shrinkage of warp and weft should be 3.5 per cent., as determined by the method of the Staatliche Materialprüfungsamts, Berlin-Dahlem. C.

**New Aliphatic Compounds: Properties and Uses.** H. B. McClure. *Chem. and Eng. News*, 1944, 22, 416-421. Aliphatic compounds which have recently become available in quantity commercially, including alcohols, Ethylbutyl Cellosolve, glycols, ethylhexanediol (mosquito repellent), water-soluble waxes and lubricants, pharmaceutical bases, water-soluble glycol-cellulose films, products for increasing the wet strength of paper, glyoxal, ketones, isophorone, various esters such as Flexol plasticizer DOP, ethyl silicate and Tergitol, various amines, amine-fatty acid condensation products, sulphur compounds and chlorinated compounds, are reviewed and their industrial uses are outlined. A table summarizes the physical properties. C.

**Plastics: Manufacture and Uses.** *Silk and Rayon*, 1943, 17, 166-8, 304-6, 442-4, 455, 705-6; 1944, 18, 216-8, 537. A popular account is given of the chemistry of plastics. The chapters deal with various uses, phenol-formaldehyde resins, and urea-formaldehyde resins. C.

**Wool-like Acetate Rayon: Production.** A. Wylezich. *Zellwolle, Kunstseide, Seide*, 1943, 48, 64-68 (through *Chem. Zentr.*, 1943, i, 2745 and *Chem. Abstr.*, 1944, 38, 1371<sup>9</sup>). Treating acetate rayon with water at 70-100° and with soap, Gardinol, etc., produces curling. This can occur also during the degumming of mixtures of acetate rayon and silk. A number of experiments were made on the treatment of fabrics under tension by boiling, and addition of soap, Gardinol, urea, etc. Soap gave a softer, fuller feel than water alone. Dyeing gave good results at 60°, but not at 100°. C.

**Raising Machine: Operation.** *Textile World*, 1944, 94, No. 3, 77, 82. A brief, illustrated account of the raising ("napping") process. In the United States, women operatives have proved to be capable machine tenders, with the foreman to make the adjustments, decide when the rollers need re-clothing and supervise oiling and greasing. C.

**Rayon Stockings: Finishing.** *Silk and Rayon*, 1944, 18, 551-552. A brief discussion of the respective methods of (1) the steam press and (2) continuous passage on the "shapes" through steaming, drying and conditioning chambers, for finishing rayon stockings. The former method usually makes the stocking  $\frac{1}{2}$ -1 inch longer in the leg, elongates the stitches, with consequent modification of the lustre, and has a polishing effect. At present, the appearance secured by the continuous process is preferred. C.

**Softening Agent Atomizing Installations.** R. Hünlich. *Deut. Textilwirts.*, 1941, 8, No. 5, 6-8 (through *Chem. Zentr.*, 1941, ii, 129 and *Chem. Abstr.*, 1944, 38, 1373<sup>1</sup>). Two-, three-, and four-cylinder MAKHA high-pressure installations are described in which the softening agents are atomized to such an extent that the fibres become uniformly moist and pliable. For scientific investigation of the softening process a special installation was built in which the number of rotations of the high-pressure pump could be varied continuously between 300 and 900. C.

**Laboratory Ink.** M. Burger. *Canadian J. Med. Technol.*, 1943, 5, 113 (through *Biol. Abs.*, 1944, B, 18, 2772). Ink for marking fabrics is composed of silver nitrate, 30; aerosol (10 per cent. solution), 1; blue-black writing ink, 1; gum arabic, 0.5, and water to make 100. Marks should be briefly exposed to ammonia. Other uses are for marking labels before autoclaving, and for glass-ware; in the latter case the mark is heated to dull redness. W.

#### (L)—PROOFING

**Cellulose Acetate-Wool Military Fabrics: Finishing.** F. Deshayes. *Teintex*, 1941, 6, 69-70 (through *Chem. Zentr.*, 1941, ii, 291 and *Chem. Abstr.*, 1944, 38, 1119<sup>3</sup>). Experiments were carried out with acetate staple fibre (Fibres N Rhodiacéta) which had been crimped, cut to lengths of 60 mm. and dyed. Because of their smoothness, the acetate fibres were not oiled but were added as such to the oiled wool. Strong alkalis should not be used in the fulling operation because of danger of saponifying the acetate fibres; the mixed material was steeped in a bath containing 8 g. ammonium hydroxide (22° Bé.) per l. The fat constituents of the wool furnish sufficient soap for the fulling. Washing is carried out with cold sodium carbonate and the fibres are waterproofed in the usual manner with aluminium chloride. C.

**Washing-resistant Water-repellent Finishes: Production.** K. Quehl. *Kleppzig's Textil-Z.*, 1943, 46, 114-117 (through *Chem. Zentr.*, 1943, i, 2651 and *Chem. Abstr.*, 1944, 38, 1120<sup>5</sup>). Methods of obtaining resistance to washing in water-repelling action are discussed critically, including the Velan process, the treatment of textiles with high-molecular isocyanates in non-aqueous solutions or aqueous emulsions, the use of casein or albumin and formaldehyde or salts, the Persistol process and Rotal impregnation. Resistance to washing may decrease slightly, especially after the third to the fifth washing, after which the effect becomes constant until the 25th and often the 50th washing. Reasons for this loss of fastness are improper concentration of liquids used, deviations from the proper impregnation technique, incorrect bath temperatures and compositions, insufficient drying of the goods after the treatment, etc. C.

**Chlorinated Phenols: Use as Preservatives and Disinfectants.** W. H. Stevens. *Chemistry and Industry*, 1944, 176. Chlorophenols are used for the preservation of wood, leather, cellulosic products, textiles, proteins, starches, adhesives, rubber latices, oils and paints, to prevent insect attack on wood, and for the control of slimes and algae in various industries, particularly those using closed cooling water systems. Pentachlorophenol, or its sodium salt, is generally used on account of its high efficiency and economy in use. *p*-Chloro-*m*-cresol is widely used for the preservation of proteins, gums, adhesives, etc., whilst for the lowest cost tar acids are employed. In some compositions, such as distempers, no great superiority has been established for chlorinated phenols over ordinary cresylic acids and it is thought that the drying oil or pigment in some way interferes with the preservation of the casein or glue by the chlorinated bodies.

cellulose sheet showed that under constant temperature and humidity conditions the air transmission rate varied with the thickness of the sheet. Increase in temperature increased the transmission rate, whilst increase of humidity reduced the rate. With regenerated cellulose, increase of humidity increased the rate of transmission. The amount of air transmitted in tests on vinylidene chloride and polyvinyl alcohol sheets during a 17-hour period was not perceptible. C.

#### PATENT

**Constant-rate-of-loading Testing Machine.** S. Denison & Sons, Ltd., H. M. H. Denison and A. Lenton. B.P.560,832 of 30/9/1942:21/4/1944. A testing machine comprises means for co-ordinating the stresses applied to the specimen with the rate of loading or counterbalancing of a steelyard on which is in part traversably mounted an adjustable poise-weight, the poise-weight also being in part mounted on and traversable along a fixed track disposed substantially parallel to the longitudinal centre line of the steelyard. The poise-weight is adjustably mounted on a trolley, the trolley being provided with a wheel bearing on the steelyard and a wheel bearing on the fixed track whereby the counterbalancing force is imparted to the fore part or front axle of the trolley. The steelyard is connected with a loading lever associated with the specimen through the medium of an intermediate lever having connection to an automatic load indicating mechanism. The angular motion of the steelyard under load applying conditions is used to control the speed of traverse of the specimen anchorage. C.

### 7—LAUNDERING AND DRY CLEANING

#### (A)—CLEANING

**Egg Albumin-Detergent Complex: Structure.** K. J. Palmer. *J. Phys. Chem.*, 1944, 48, 12-21. A structure for a denatured egg albumin-detergent (Nacconol NRSF) complex is postulated which appears to be in agreement with the results of an electrophoretic investigation of this system by Lundgren, Elam and O'Connell. It consists of a polar protein monolayer with the detergent molecules adsorbed on one side only and with the long axes of the detergent molecules perpendicular to the protein layer. From this structure it is suggested that the polar amino acids probably alternate along the peptide chain in egg albumin. It follows that if the layer structure for native egg albumin postulated by Pauling is acceptable, the layers in the native configuration are polar. By use of this model a plausible structure is postulated for the complex which forms between native egg albumin and detergent. This structure appears to account for the observed facts that the complex formed from native egg albumin never contains less than 25 per cent. of Nacconol NRSF (whereas that formed from denatured egg albumin does), and that the complex containing 75 per cent. native egg albumin and 25 per cent. detergent can exist in equilibrium with free native protein. C.

**Soap Suspensions in Mineral Oil: Sedimentation Volumes and Rigidity.** W. Gallay and I. E. Puddington. *Canadian J. Res.*, 1944, 22, B, 16-20. The equilibrium sedimentation volumes of sodium soaps in suspension in mineral oils volume increase greatly with decrease in viscosity index of the oil. Flow/pressure relations, determined with a torsional viscometer, show that suspensions with large sedimentation volumes possess rigidity, whereas the flow is Newtonian in suspensions having small sedimentation volumes. Variation in sedimentation volume is therefore caused by difference in the tendency toward agglomeration or attraction between particles, leading to the formation of branched chains and scaffolding structures, with consequently greater sedimentation volumes. C.

**Trichloroethylene: Vapour Pressure.** H. J. McDonald. *J. Phys. Chem.*, 1944, 48, 47-50. Determinations of the vapour pressure of trichloroethylene in the range 18-86° C. are described and the results tabulated. The vapour pressure-temperature relation is expressed in the form of an equation. The heat of vaporization at the boiling point (87.19° C.) and 1 atm. pressure is found to be 7,679 cal. per mole, with an estimated mean error of  $\pm 100$  cal. Equations are given for the variation of density and refractive index with temperature. C.

**Dyed and Printed Cotton Fabrics: Fastness to Washing.** See Section 5C.

## PATENTS.

**Improvements in Detergent Compositions and Methods of Production.** F. D. Snell. B.P.561,294. Conv. (U.S.) 30/12/41. Appl. 4/6/42. Acc. 15/5/44. The invention comprises a detergent composition, including a water-soluble, ionisable, anionic surface-active compound, stable in alkaline solution, and a material containing sodium oxide and boron trioxide, whether fully combined or not. An example is composed of a water-soluble soap and sodium metaborate, and variation includes a calcium sequestration agent. Tests have been made in a launderometer and considerable increase in brightness, due to the addition of a borate material according to the invention was noted, even when the soap to which the detergent was compared was of a higher pH value. La.

**Improvements in Laundry Ironing Machines.** (1) D. & J. Tullis, Ltd. and R. Wilson. B.P.561,268. Appl. 6/10/42. Acc. 12/5/44. (2) I. M. Fisher. B.P.561,371. Appl. 14/10/42. Acc. 17/5/44. (1) The ironing machine consists of a stationary bed made up from a series of hollow box-like members arranged to form a plane continuous ironing surface, which can be internally heated. An endless conveyor band is mounted above the bed so that articles to be ironed are carried along in contact with the bed and are discharged from the other end of the machine. A number of padded float-irons or platens are fitted to apply suitable ironing pressure. (2) The ironing machine is designed particularly for the ironing of small articles such as handkerchiefs. A padded roller is provided, of the type commonly provided in power ironing machines, and this is adapted to be driven intermittently by a pedal or by the operator. Above, there is a clamping member, such as a polished bar, which can be mechanically raised or lowered as required. This clamp holds the handkerchief or other article straight until it passes between the rollers and the heated bed. The machine is then stopped automatically or by a pedal and another handkerchief is clamped on to the roller and the machine is restarted. It is claimed that by this means the handkerchief is less liable to crease and that, due to the periods of rest afforded to the roller, a greater rate of feed may be effected than is possible with a machine that is equipped with a continuously rotating roller of the same diameter and construction. The clamp may also constitute a safety guard for the fingers of the operator. La.

## 8—BUILDING AND ENGINEERING

## (A)—CONSTRUCTION AND MAINTENANCE OF BUILDINGS AND PLANT

**Glass Fibre Distillation Column Packing Material: Application.** G. W. Minard, J. H. Koffolt and J. R. Withrow. *Trans. Amer. Inst. Chem. Engrs.*, 1943, 39, 813-851 (through *Chem. Abstr.*, 1944, 38, 897<sup>9</sup>). This paper summarizes the results of some 600 tests of the use of glass fibre as a packing material for 1 ft. diameter columns. The work was done on a distillation column packed to a height of 6½ ft., and another packed to a height of 1½ ft. Data are reported for the concentration of aqueous solutions of ethyl alcohol, methyl alcohol and acetone. The effects of reflux ratio, vapour velocity and composition are summarized. The investigation indicates that glass fibre is characterised by (1) good rectifying performance, (2) high rate of throughput with low pressure drop, (3) low hold-up, (4) light weight per unit volume, (5) consistent behaviour, and (6) low cost. C.

**Cotton Sliver: Application in Marine Caulking.** J. L. Crane and S. Williams *Cotton (U.S.)*, 1944, 108, No. 2, 93-95. Because of the shortage of jute and hemp, the U.S. Navy authorities have made tests on the use of cotton sliver for caulking deck seams. Hitherto, cotton has been used for small boats and also in conjunction with oakum (hemp impregnated with pine tar and the like), but users have claimed that it tends to spring out of the seams before the glue is applied. To meet this difficulty, the tested materials included cotton sliver impregnated with castor oil, but this was not found satisfactory, partly because it clung to the caulking iron. The tests reported show, in fact, that plain cotton sliver is satisfactory as a caulking material, though a pound of it does not fill such a length of seam as a pound of standard oakum. It is recommended that the sliver should run 250 ft. to the pound and be supplied in reels, spools or balls. The desirable features of a caulking material are listed. They include low moisture absorption, and one of the tables of test data records regains after various periods at 70° F. and 65 or 100 per cent. R.H. C.

**"Mark 2 Black" Rust-proofing Agent.** Metal Processes Ltd. *Practical Engineering*, 1944, 9, 454-455. "Mark 2 Black" is a simple and quick process for imparting to iron and steel rust-resisting and abrasive-resisting qualities. The agent is supplied in powder form and gives a strongly alkaline solution. Except with articles having large dead flat surfaces, treatment is effected in mass in basket loads by immersing in the simmering solutions for some minutes, first in No. 1 tank (275-280° F.) and then in No. 2 tank (300-310° F.), afterwards swilling and drying off automatically in special hot oil. Details of the procedure are given. Articles should preferably be degreased before treatment. Any scale or oxide should be removed before treatment. The treatment is applicable to iron and steel, including wrought iron, malleable iron castings, or wrought iron cast steel, but not to grey iron castings or stainless steel and some high-duty steels. C.

**Masonite Hydrolysed Wood Products: Production.** R. M. Boehm. *Paper Trade J.*, 1944, 118, TAPPI, 109-112. The Masonite process consists of a steam explosion treatment in which wood chips are treated for a very short period with steam at a pressure of 1000 lb. per sq. in. The steamed chips leaving the gun are exploded into a brown, fluffy mass of moist fibre which may be formed into sheets and fed to hydraulic presses for the manufacture of insulation and pressed fibre products varying in specific gravity from 0.02 to 1.44. In the early stages of the steaming operation considerable quantities of acetic and formic acids are formed which produce acid hydrolysis. Hemicellulose is largely converted to a water-soluble or -dispersible condition and is removed by a washing operation. The lignin-carbohydrate bond is broken. The cellulose portion is not greatly changed. The lignin undergoes a considerable degree of depolymerisation so that it is activated and in a suitable condition for re-exerting its bonding powers when subjected to the proper conditions of moisture, temperature and pressure. The bonding effect is to a considerable extent thermosetting, resembling that of synthetic resins. A modification of the normal process, which involves initially converting the fibre to a semiplastic condition, has made possible the production of materials of great density and thickness suitable for the construction of dies for forming and cutting metal parts for aircraft. Other modifications have made possible the production of dense, strong and water-resistant panels and lofting board for use in aircraft and ship building industries, hardboard for the construction of fluorescent lighting reflectors, and formed articles such as ice boxes, chair seats and backs. C.

**Metallic Machine Components: Non-destructive Testing.** B. Chalmers. *Proc. Phys. Soc.*, 1944, 56, 132-147. Non-destructive indirect methods of measuring the dimensions of metallic components and non-destructive tests for flaws, tests of physical properties related to mechanical properties, and tests for surface protection and surface profile are reviewed. A report is given of a discussion in which further details of some of the methods were given. C.

**Plastic-impregnated Wood: Production and Properties.** L. Klein, H. Grinsfelder and S. D. Bailey. *Ind. Eng. Chem.*, 1944, 36, 252-256. Methods of improving the physical properties of wood involving (1) impregnation with phenolformaldehyde resin followed by compression, (2) application of heat and pressure to an assembly of veneers interleaved with resin film, and (3) application of liquid resin to veneers by resin glue spreaders, followed by the application of heat and pressure, are reviewed and their advantages and disadvantages compared. Data are presented showing the dimensional stability to water and heat, tensile strength, impact strength, ease of compression, shear strength, modulus of elasticity in bending, modulus of rupture, ease of manufacture, surface appearance, and cost of products of the three processes. It is pointed out that the choice of material will depend upon its intended use, and various fields of application are mentioned. C.

**Porous Non-ferrous Castings: Sealing.** Bakelite Ltd. *Practical Engineering*, 1944, 9, 458-459. The Bakelite sealing process has proved ideal for the treatment of inter-crystalline porosity in non-ferrous castings caused by high pouring temperatures, inadequate feeding, or the presence of gas. The sealing material is stable under the majority of service conditions and is unaffected by water, steam up to 205° C., oil up to 135° C., diethylene glycol, petrol and other organic solvents, and most chemical reagents except concentrated sulphuric

and nitric acids and hot caustic alkali. Before treatment the castings should be free from liquids used for previous pressure tests, e.g. water, paraffin or oil. All exits on the casting should be closed except those to be used for filling the casting with the sealing solution and removal of displaced air. When the casting is filled, pressure is applied by means of a hand pump or by the use of compressed air. The pressure applied should preferably be high enough to force the Bakelite solution through the porous area to the outside of the casting. The casting is then emptied and wiped, and placed in a well-ventilated stove. Heat is applied so that during the first hour the casting is brought up to a temperature of about 85° C. and held for one hour. After the solvents are removed the temperature is raised to about 110° C. for an hour and finally to 135-170° C. for a similar period to ensure complete polymerisation. Successful applications of this process to various types of castings are reported. C.

#### (B)—FIRE PREVENTION

**Softening Agents: Fire Hazard.** Metz and Borchert. *Arbeitsschutz*, 1941, 93-97 (through *Chem. Zentr.*, 1941, ii, 134 and *Chem. Abstr.*, 1944, 38, 1373<sup>3</sup>). The fire hazard of unsuitable softening agents is discussed. Poly-unsaturated fat acids are the principal cause of spontaneous ignition. Primary peroxides are produced, and these act as powerful oxidising agents with the evolution of heat to cause spontaneous ignition. Unsaturated acids can be detected by means of the iodine number. The difference between the iodine and the thiocyanogen numbers gives the amount of poly-unsaturated acids. The Mackey test is a measure of spontaneous ignition. Experiments on softeners showed the value of the Mackey test. Iron is an effective oxidation accelerator. Directions are given for the Mackey test and for iron determination. The determination of pH with the universal indicator "Merck" or with Lyphan paper is discussed. The influence of softeners on iron is described. Softeners approved by the Staatliche Prüfungsamt are listed. C.

#### (C)—STEAM RAISING AND POWER SUPPLY

**Steam and Water Piping: Maintenance.** F. D. Mosher. *Textile World*, 1944, 94, No. 3, 96-97. Practical advice is given on the inspection of piping, valves and traps, on locating leaks in pipe covering, on improving the drainage of piping, and on the value of welding for repairs. C.

**"Electrode" Steam Raising Plant: Advantages.** Messrs. Bastian and Allen Ltd. *Textile Mercury and Argus*, 1944, 110, 488. For many textile mills requiring up to about 3,000 lb. of steam per hour, an electric boiler may be an economical proposition. Boilers of the a.c. "electrode" type are available in units that evaporate 75-3,250 lb. of water per hour at gauge pressures up to 120 lb. per sq. in. The efficiency is 98 per cent. so that almost all the 3,412 B.Th.U.'s equivalent to one k.W.h. are available. The boilers are lagged with 2-in. magnesia-asbestos blocks encased in planished steel and range from 3 ft. 6 in. to 8 ft. 2 in. in height and 1 ft. 7 in. to 3 ft. 4 in. in diameter. C.

#### (D)—POWER TRANSMISSION

**Driving Shaft: Stresses; Graphical Solution.** G. A. Pickett. *Engineering*, 1944, 157, 361-362. A graphical method of analysis, dealing with loadings which lie wholly in two planes, which is only applicable to circular shafts, is explained and illustrated by a study of examples. C.

**Second-hand Electrical Machinery: Selection.** *Silk and Rayon*, 1944, 18, 561-562. Practical advice is given on points to check when purchasing second-hand motors and their control gear, including tests of the insulation. C.

**Lubricating Oils: Corrosive Effect.** G. W. Waters and H. D. Burnham. *Ind. Eng. Chem.*, 1944, 36, 263-271. The corrosive effect of oils on bearings is analysed into two types: "existent corrosivity" which occurs by virtue of the instantaneous chemical state of the lubricant, and "potential corrosivity" which occurs under conditions, representative of those of service, which lead to the simultaneous oxidation of the oil. Reference is made to apparatus for measuring potential corrosivity and details are given of an apparatus and procedure for measuring existent corrosivity. The effects upon both types of corrosivity of temperature, time, nature of oil, concentration of reactants, and physical factors of tests are studied, and data obtained in tests of various oils

on various metals and alloys are presented in tables and graphs. The effects of oils containing acids and the effects of addition of detergents are discussed. C.

**Wool Baling Machine.** F. D. Snyder. *Text. World*, 1943, 93, No. 12, 95. The operation is described and illustrated of an electric drive for a wool baling machine. A plunger is pushed against the wool in the bale with the same pressure each time the plunger is made to go down. Bales are filled within 3 per cent. of the same weight. W.

(E)—TRANSPORT

**Warp Beam Transport System.** F. A. Westbrook. *Textile World*, 1944, 94, No. 2, 114-115. Illustrations are given of an overhead tramrail system for handling (and weighing) beams in the warping and sizing department of an American mill. It is expected to pay for itself in about a year. C.

(G)—HEATING, VENTILATION AND HUMIDIFICATION

**Radiant and Inductive Heating Appliances: Industrial Applications.** L. J. C. Connell. *G.E.C. Journal*, 1944, 13, 10-32. The characteristics of the various methods of heating are discussed and radiation and convection methods are compared. Lamps used as sources of radiation are described and an account is given of applications of lamp heating for drying paints, coil varnishes and foundry moulds, accelerating the setting of adhesives, drying fabrics and curing coated and impregnated materials, softening plastics, and various other purposes. Sources of radiation operating at temperatures lower than that of the lamp filament are discussed. Capacity current heating, wherein the material to be heated is made the dielectric of a condenser, the plates of which are connected to a source of radio-frequency power, and its applications in the production of laminated wood and laminated plastic materials, the drying of rayon yarn, the pre-heating of plastic moulding materials, and the joining of thermo-plastic materials are described. Eddy current heating, which consists in the production of alternating currents in the material by exposing it to an alternating magnetic field and is particularly suitable for surface hardening operations, is discussed. C.

**Steam Chamber Thermocouple: Sealing.** S. Munday. *J. Sci. Instruments*, 1944, 21, 67. A method of sealing electrodes into a steam chamber in such a way that no leakage of steam past the wires or insulators takes place is described and shown diagrammatically. C.

**Fans: Selection.** B. B. Daly. *G.E.C. Journal*, 1944, 13, 33-40. A summary is given of the laws of fan operation, together with typical performance data for the more common types. It is shown that, whilst the prediction of fan performance is straightforward, the converse problem of selecting a fan for a given performance is soluble only by trial and error or by cumbersome and little used "specific speed" and allied methods. A description is then given of a method for the ready solution of both performance prediction and fan selection problems, which employs a logarithmically divided ground chart common to all types of fan and covering a wide range of air-flow, fan static pressure, diameter and speed, over which moves a sheet of transparent material (cursor) on which is drawn a curve characteristic of a particular family of fans. C.

**High-frequency Heating Apparatus: Applications in the Plastics Industry.** A. E. L. Jervis. *Electrical Review*, 1944, 134, 728-731. High-frequency power can be used (a) for drying materials such as paper, tobacco, clays, ceramic articles, and wood, (b) for partial pre-heating of mouldings and laminates, e.g. propeller blade blocks, and (c) for complete heating and curing of mouldings and laminates. Curves are given showing the saving of time in comparison with steam heating, and also the relationship of curing time to thickness of moulding with conventional and high-frequency pre-heating. Operating and equipment costs of high-frequency heating are discussed and some approximate estimates are given. C.

(H)—WATER PURIFICATION

**Alginates: Use for Water Softening.** Pinnington, Dawson & Wood, Ltd. *Chemistry and Industry*, 1944, 187-188. By the steady use of sodium alginate, hard scale, in some parts  $\frac{1}{4}$ -in. thick, has been removed from boiler tubes. The water used in this particular works is drawn from a well fed by a spring and is rather over the medium in both temporary and permanent hardness and con-

tains substantial quantities of dirt and organic matter. Sodium alginate combines with the calcium to form an insoluble globular mass, which in turn envelops other sediment and precipitates, giving a soft pasty sludge. Much of this sludge can be blown out of the boiler at regular intervals and it is possible to swill off the sludge from tubes with a hose pipe. C.

**Water Filtration Plant.** J. D. Joseph. *Textile Manufacturer*, 1944, 70, 176-179. An illustrated account is given of modern plant for filtering water for industrial purposes, combined with chemical treatment for removing colloidal matter, iron and manganese, and objectionable odour. C.

#### (I)—WASTE DISPOSAL

**Textile Waste Liquors: Effect on Sewage Disposal.** C. R. Hoover. *Public Works*, N.Y., 1942, 73, No. 11, 32 (through *Water Pollution Res. Summ. Current Lit.*, 1943, 16, 124). Investigations at Middletown, Conn., on the effect of industrial wastes on common methods of sewage disposal are described in a report to the State Water Commission of Connecticut. When a very toxic component had been removed, up to 10 per cent. of typical composite textile waste could be added to the sewage without seriously affecting digestion of sludge. Copper in sewage tends to become concentrated in the sludge; sludge from sewage containing 0.5 p.p.m. copper was found to contain over 100 p.p.m. copper and digestion was impaired. Copper in sewage is not always due to industrial wastes; it may be present as the result of treating reservoirs with copper sulphate or of using copper pipes in domestic hot-water equipment. When the concentration of copper in sewage exceeds 1 p.p.m. digestion of sludge is usually affected, but it is probable that harmful effects of concentrations up to 1.25 p.p.m. can be reduced by addition of small amounts of a soluble sulphide. Copper can be removed from acid waste waters by filters of scrap iron, and from alkaline waste waters by treatment with sodium or calcium sulphides followed by copperas. Chromates do not accumulate in the sludge nor interfere with digestion to the same extent as copper compounds, but when 200 p.p.m. precipitated chromium is present in sludge, the rate of digestion is noticeably reduced. When more than 1 p.p.m. chromium is present in sewage received at a sewage works, chromium should be removed at the source. C.

**Wool Scouring Liquor: Recovery of Potassium Carbonate and Conversion to Commercial Potassium Sulphate.** P. K. van der Merwe. *Onderstepoort J.*, 1943, 18, 321-326. Suint from South African wool contains some potassium sulphate derived from (1) a sulphate-containing ground and burned veldt ash contamination of the wool, (2) the dipping of sheep in sulphate-carrying waters. Potassium carbonate from wool scouring liquor was converted to potassium sulphate on a commercial scale by a simple cation exchange reaction, using natural gypsum as the source of sulphate. W.

**Lanolin.** E. S. Lower. *Manufacturing Chemist*, 1944, 15, 13-16, 35, 68-71. The various qualities of lanolin now obtainable on the British market are summarised. Its properties are discussed, and an average analysis given of various grades. Its uses and those of its derivatives are described in detail. W.

#### PATENT

**Viscosity Regulator.** A.-B. Aerotransport (Stockholm). B.P.561,122 of 30/11/1942: 5/5/1944 (Conv. 29/11/1941). A viscosity regulator for a flowing medium, e.g. lubricating oil in engines, in which a valve device which is controlled by the pressure differential which occurs across a friction channel inserted in the path of the medium and varies as a function of the viscosity of the medium, regulates the two branch currents of the medium flowing to and by-passing a heat exchanger respectively, or two mixture components delivered to a mixer, in such proportions that a predetermined viscosity of the medium is maintained after the branch currents or the components have been mixed is characterised in that a differential piston or equivalent means which is actuated in one direction by the pressure differential across the friction channel and serves for the control of the valve device is actuated in the opposite direction by the pressure differential across a restricted passage of short axial length connected in series with the friction channel, the latter pressure differential being a function of the velocity of the medium, but substantially independent of the viscosity, and that the areas of the piston subjected to the opposed pressure differentials of said passage are so proportioned that the pressure differential

across the latter substantially neutralizes the influence on the piston or the like of such variations in the pressure differential across the friction channel as depend on variations of the velocity of the medium. C.

## 9—PURE SCIENCE

**Iron: Colorimetric Determination.** J. H. Yoe and A. L. Jones. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 111-115. Disodium 1:2-dihydroxybenzene-3:5-disulphonate is a sensitive and stable reagent for the colorimetric determination of ferric iron. The preparation of reagent and buffer solutions and a recommended analytical procedure are described. The nature of the reaction and the chemical behaviour of the coloured ferric complexes, as revealed by visual and spectrophotometric studies, are discussed. The coloured complexes (red in alkaline medium, blue in acid) obey Beer's law over the useful range of iron concentrations. In alkaline solution ( $pH$  9 to 10), the reagent is sensitive to one part of iron in 200,000,000 parts of solution when observations are made in Nessler cylinders. In acid solution ( $pH$  3.5 to 4.5), the sensitivity is one part in 30,000,000. In tests of the reagent with 78 ions, only 7 produced coloured solutions; the reaction with Ti (yellow) was the most intense. Only ferric iron gave a blue or red solution. Copper produced a greenish yellow colour in alkaline solution. By utilising the red complex, which is completely stable in alkaline solution, iron may be determined in the presence of large amounts of fluoride, tartrate, oxalate, citrate, or phosphate. C.

**Cellulose Ester Plasticizers: Determination.** B. S. Biggs and R. H. Erickson. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 93-94. For the determination of plasticizer content, dry samples of 1 g. or less are placed in weighing bottles, 3 c.c. of acetylacetone are added to each, and the bottles are placed in a special vacuum still in which the temperature is maintained at 256° C. by boiling "Dowtherm." Heating is continued for 1½ hours. The loss in weight is due to plasticizer plus a slight decomposition of the cellulose ether. The latter is determined on a blank, but is usually so small and uniform that a fixed value may be assumed for it. Reproducible results have been obtained with samples of cellulose acetate and acetate-butyrate containing diethyl phthalate, dibutyl phthalate, dibutyl sebacate and butyl stearate. C.

**Dicarboxylic Amino Acids: Determination in Protein Hydrolysates.** R. K. Cannan. *J. Biol. Chem.*, 1944, 152, 401-410. The essential steps in procedures for the determination of glutamic and aspartic acids in protein hydrolysates are the adsorption of the acids from the hydrolysates by the basic resin, Amberlite IR-4, followed by their elution with hydrochloric acid. The solution obtained contains no more than traces of amino acids other than the dicarboxylic acids. From it, glutamic acid hydrochloride and copper aspartate may be crystallized directly in pure form. Results obtained in the analysis of egg albumin,  $\beta$ -lactoglobulin and edestin are compared with results obtained by other methods. C.

**Polymerised Drying and Semi-drying Oils: Analysis.** J. C. Cowan, L. B. Falkenburg and H. M. Teeter. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 90-92. Details are given of a procedure for the determination of polymers in a heat-bodied vegetable oil which involves conversion to the methyl esters, removal of unpolymerised esters by distillation at 5 to 10 mm., and fractionation of the polymerised products by distillation at 1 mm. or less. The refractive index of each fraction collected is plotted against the total per cent. distilled up to the mid-point of that fraction, and a smooth curve is drawn. The percentages of monomeride, intermediate, dimeride, and higher polymers are determined from the graph. Results are given for bodied soybean, linseed, perilla, and tung oils. C.

**Vegetable Matter: Nitrogen, Phosphorus and Potassium Determination.** B. Wolf. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 121-123. Rapid photometric methods for the determination of total N, P and K in plant materials are presented. The material is rapidly decomposed by means of sulphuric acid and hydrogen peroxide and separate portions of the digest are used for the three determinations. The analysis for N involves the use of Graves' reagent and caustic soda, that for P the use of ammonium molybdate and aminonaphtholsulphonic acid, and that for K the use of sodium cobaltinitrite and isopropyl alcohol. Photometer readings are taken with a Fisher electrophotometer using appropriate

filters. Concentrations are read from standard curves or charts. The results obtained are less accurate than those obtained by the methods of the Association of Official Agricultural Chemists but are sufficient for many routine purposes. C.

#### (E)—ORGANIC CHEMISTRY

**Cellulose Primary-valence Gels: Formation.** R. Signer and P. v. Tavel. *Helv. Chim. Acta*, 1943, 26, 1972-1978 (through *Chem. Abstr.*, 1944, 38, 9067). Highly methylated cellulose, existing as linear macromolecules in dilute chloroform solution, was treated with oxalyl chloride, with traces of tertiary base added to fix the liberated acid, so that a clear gel resulted. The rate of formation of such a gel was studied as a function of the concentration of the reactants and of the amount of base present. C.

**Limit Dextrins: Formation and Composition.** (1) B. Ortenblad and K. Myrback. (2) K. Myrback, B. Ortenblad and K. Ahlberg. (3) K. Myrback and B. Kihlberg. *Biochem. Z.*, 1943, 315, 233-239, 240-249, 250-258 (through *Chem. Abstr.*, 1944, 38, 9849). (1) Dextrinogen amylase acts in two phases: (a) dextrinization, and (b) saccharification, the former being 20-50 times more rapid than the latter. The rate of reaction falls off suddenly when about 16 per cent. splitting has been attained. The products of the first phase are  $\alpha$ -dextrins. The conclusion is therefore drawn that the splitting occurs only at certain bonds. Studies with the enzyme show that both glucose and maltose are formed in the hydrolysis of a specially prepared starch substrate. The glucose represents about 15 per cent. of the maltose, and the substrate concentration has scarcely any effect on the reaction. Experiments with  $\alpha$ -dextrin show that the hydrolysis starts as a very rapid reaction, but soon slows down greatly and, as in the case of starch, glucose is also formed (about 20 per cent.). The dextrinogen amylase, therefore, is a special type among the amylases. (2) Fractionation of non-fermentable products obtained from different starches with malt extract or taka-diastase shows that limit dextrins are always mixtures of saccharides of different chain length, especially hexa- and tetrasaccharides. It is suggested that tetra- and tri-saccharides may originate from hexasaccharides through the action of some special enzymes. (3) The phosphorus content of various starch limit dextrin fractions appears to decrease with decrease in molecular weight of the respective fractions, although experiments with glycerophosphate show that, except for pancreatin, every amylase preparation used has phosphatase activity. C.

**Starch: Two-component Structure.** B. Brimhall and R. M. Hixon. *Wallerstein Lab. Comm.*, 1943, 6, 95-100 (through *Brit. Chem. Abstr.*, 1944, A II, 39). Evidence supporting the two-component theory of starch structure is presented. Methods for separating amylose (straight chain) and amylopectin (branched chain) are outlined, and the properties of these components discussed, variations between starches of different origin being noted. C.

**Casein Hydrolysis Products: Characteristics.** T. Winnick. *J. Biol. Chem.*, 1944, 152, 465-473. A study was made of the partial hydrolysis products from the action on casein of the enzymes pepsin, trypsin, chymotrypsin, ficin, and papain. Following digestions with the proteases, the average non-protein molecules contained from 5 to 7 amino acid residues. Values for carboxyl nitrogen indicated that 1 to 3 per cent. of the total nitrogen was in the form of free amino acids. The ratios of carboxyl nitrogen to the amino nitrogen freed by complete acid hydrolysis indicated that from 1.5 to 4.5 per cent. of the total amino acids of casein was liberated by protease action. Percentages of amino and carboxyl nitrogen were not altered significantly by electro dialysis of the digestion products. Specific rotations and molecular weights of the electro dialysed products were determined. The further action of carboxypeptidase on protease digests of casein was studied and interpreted as the splitting of free amino acids from the ends of polypeptide chains. The initial products from short periods of protein digestion were compared with those from prolonged protease action. The specific rotations and ratios of amino to total nitrogen of the products did not differ significantly in the two cases, in agreement with the view that relatively few protein molecules are split rapidly in each time interval in enzymic hydrolysis. C.

**Proteins: Reaction with Formaldehyde.** K. H. Gustavson. *Kolloid Z.*, 1943, 103, 43-54 (through *Brit. Chem. Abstr.*, 1944, A II, 27). The tanning effect of formaldehyde on proteins is discussed. Fibrous proteins, e.g. collagen, are more easily studied than water-soluble proteins, since they have measurable properties altered by formaldehyde treatment. Properties studied are temperature of contraction, swelling in water, and degradation by trypsin. In dilute formaldehyde solutions irreversible formaldehyde fixation is due to the  $\epsilon$ -NH<sub>2</sub> groups of lysine in the pH range 5-8, and the NH<sub>2</sub> groups of arginine at pH greater than 8. In concentrated solutions secondary reactions occur. Formaldehyde combines with partly deaminated collagen freed from primary NH<sub>2</sub> groups, but does not have a tanning effect. Thus the formaldehyde attached to NH<sub>2</sub> groups of arginine residues does not stabilise collagen chains by cross-linking; tanning by formaldehyde results from formation of cross-linkings between  $\epsilon$ -NH<sub>2</sub> groups of lysine in neighbouring chains. In acid solutions native collagen shows a tanning effect at high formaldehyde concentration, but deaminated collagen is unchanged. Formaldehyde fixation is a slow reaction in this case. Formaldehyde is also taken up by peptide groups, but is not then involved in cross-linking and stabilising the structure. Formaldehyde is also effective in organic solvents. C.

**Laurylsulphonic Acid: Migration Data; Interpretation.** P. Van Rysselberghe. *J. Phys. Chem.*, 1944, 48, 62-65. Migration data obtained by E. L. McBain for laurylsulphonic acid in aqueous solution are shown to indicate the presence of rather large amounts of nearly neutral micelles with compensating migrations at concentrations above the maximum in the transference curve. Below the maximum the transference numbers are in excellent agreement with the values calculated on the basis of a previously calculated average micelle whose composition and size change continuously with concentration. C.

**Sodium Alcohol Sulphates: Surface Tension/Concentration Curves.** G. D. Miles and L. Shedlovsky. *J. Phys. Chem.*, 1944, 48, 57-62. The surface tension/concentration curve for pure sodium dodecyl sulphate which had been extracted with ether does not show any minimum, but a minimum is observed in the curve for the same product before the final extraction with ether. Addition of small proportions of dodecanol to the pure sodium dodecyl sulphate causes the appearance of a minimum in the curve. Addition of sodium hexadecyl sulphate has a similar effect. Similarly, pure ether-extracted sodium tridecane-2-sulphate gives a surface tension/concentration curve without a minimum, but minima are observed in the presence of small amounts of sodium pentadecane-2-sulphate or heptadecane-2-sulphate. These results indicate that minima may be produced by (1) the presence in the solution of two surface-active materials, one of which is only slightly soluble in water, and (2) the presence of two anionic surface-active electrolytes. The explanation of the observed effects is briefly discussed. C.

**Cupriethylene Diamine Cellulose Solutions: Viscosity.** R. S. Hatch. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 104-107. A method is described for the precise determination of cellulose viscosity with cupriethylene diamine as solvent. Measurements are made of the time of fall of a  $\frac{1}{16}$ -in. aluminium sphere through a distance of 18 cm. in a 1 per cent. solution. Details are given of the preparation of the cupriethylene diamine solution and the calibration of the viscosity tubes. The preparation and solution of pulp samples for precise determinations and for rapid determination for mill control purposes are described. C.

**Gelatin and Glues: Differentiation.** A. Steigmann. *J. Soc. Chem. Ind.*, 1944, 63, 96. Relatively small differences in the setting point and viscosity of gelatins and glues are greatly exaggerated by taking the setting point of cold urea-gelatin solutions, or by addition of Teepol or similar anionic detergent to gelatin or glue solutions. Teepol increases the viscosities of such solutions and magnifies the differences as shown by the standard methods. Urea in high concentrations, though preventing the formation of a gelatin gel, does not decrease, but rather increases the viscosity under standard conditions (6½ per cent. solution: 40°). A setting-time test using solutions containing urea and a viscosity test with solutions containing Teepol are described. Viscosity data are given for solutions of different grades of gelatin, with and without Teepol. C.

**Macromolecular Systems: Viscosity and Chemical Constitution.** H. Umstätter. *Kolloid Z.*, 1943, 103, 7-18 (through *Brit. Chem. Abstr.*, 1944, A I, 14). A viscosity-concentration function incorporating Staudinger's relation is derived thermodynamically, and the limits of its validity are examined. Macromolecules are non-rigid and can therefore absorb part of the energy of solvent molecules on collision. Such inelastic collisions result in the formation of a sheath of solvent molecules around the solute molecule; solvation is thus accounted for without assumption of any special forces. Determination of particle size is possible from the flow curve and viscosity-temperature function. Large molecules may rupture if the molecular cohesion between neighbouring chains is greater than the chain strength. There is thus an upper limit to molecular size above which molecules are mechanically unstable. C.

**Rubber Derivatives: Viscosity.** Hermann Staudinger and Hansjürgen Staudinger. *J. prakt. Chem.*, 1943, 162, 148 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1943, B:115.1). The  $K_m$  values ( $K_m = Z_n/P$ , where  $Z_n = \lim_{c \rightarrow 0} \eta_{sp}/c$  and  $P = M/G_m$  where  $M$  is the average molecular weight, determined osmotically and  $G_m$  is the basic molecular weight) have been determined for various derivatives of rubber, balata and similar materials. With squalene and its hexahydrochloride, which serve as models for the substances of lower molecular weight, the halogen derivative has a higher value of  $K_m$ . With the hydrochlorides of balata and rubber, the  $K_m$  values are lower than those for the corresponding hydrocarbons. Apparently, the long molecules of the polyprene are shortened by a cyclization reaction in which the chlorine content falls below the theoretical value for the hydrochloride. The  $K_m$  values of the ethylpolypranes are similar to those of the hydrochlorides or slightly higher, and less than those of the original hydrocarbons. It follows that the decrease in  $K_m$  values from the hydrocarbons to the hydrochlorides is not due to a greater degree of coiling of the molecule because of the reciprocal attraction of the chlorine atoms. The  $K_m$  value of bromobalata is of the same order of magnitude as that of the hydrochloride, apparently on account of the same chain-shortening cyclization reaction. The  $K_m$  value of chloroprene is of similar magnitude to that of rubber, balata and Buna. This is further proof that the lower  $K_m$  values of polyprene hydrochloride cannot depend upon a coiling of the long molecules occasioned by mutual attraction of the chlorine atoms, but must be conditioned by a cyclization. In spite of the low viscosity of their solutions, the chlorinated rubbers have a very high molecular weight. Therefore, since chlorinated rubber, chlorinated balata, and chlorinated Buna are not decomposed by the chlorination process, the low viscosity of their solutions can only be explained by the assumption of a cyclization reaction which produces a marked shortening of the molecule. The  $K_m$  values of the chlorinated products are only about one-fifth those of the original rubbers and therefore a very considerable shortening of the chain must occur. This may be explained by postulating for the macromolecules of rubber, balata and Buna, a branched configuration whereby the side chains may react with the main chain, thus producing a marked shortening of the molecules. C.

**Fatty Acids: Conjugation; Determination from Absorption Spectra.** W. R. Brode, J. W. Patterson, J. B. Brown and J. Frankel. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 77-80. A method of determining the amount of 2-, 3- and 4-double bond conjugation in the presence of non-conjugated fatty acids by means of absorption spectra is explained and the application of the method to the analysis of samples of linoleic acid is described. The results indicate that the crystallisation method of purification gives products of lower total conjugation than those obtained by debromination of the tetrabromide. The conjugation rearrangement is probably caused by the zinc bromide formed during the debromination. The amount of conjugation varies with the solvent used. C.

**Carcinogenic Hydrocarbons: Fluorescence.** J. A. Miller and C. A. Baumann. *Cancer Research*, 1943, 3, 223-229 (through *Brit. Chem. Abstr.*, 1944, A I, 28-29). The intensity of fluorescence in solution has been measured for seven hydrocarbons in 37 solvents. In most solvents fluorescence increases progressively in the order: naphthacene, 1:2:5:6-dibenzanthracene, 1:2-benzanthracene, anthracene, 9:10-dimethyl-1:2-benzanthracene, 20-methylcholanthrene, 3:4-benzpyrene. Fluorescence is most intense in tetrahydrofurfuryl

alcohol, pyridine, glycol monomethyl ether, and dioxan; it is low in the lower alkanes, and zero in carbon disulphide or aniline. The fluorescence of these hydrocarbons, with the exception of 1:2:5:6-dibenzanthracene, is partly destroyed in solution by prolonged exposure to ultra-violet. Each hydrocarbon is stable to refluxing in 10 per cent. alcoholic potash for 1 hour. The most potent inhibitor of fluorescence is tetranitromethane. The inhibition is irreversible. The fluorescence of the unsaponifiable matter of mouse tissue has been measured in 18 solvents. The fluorescence is very weak as compared with that of the hydrocarbons and does not vary greatly with solvent. In mixtures it is strictly additive to the hydrocarbon fluorescence. C.

**Polynuclear Hydrocarbons: Fluorescence; Effect of Naphthacene.** J. A. Miller and C. A. Baumann. *Cancer Research*, 1943, 3, 217-222 (through *Brit. Chem. Abstr.*, 1944, A1, 28). Details are given for the purification of carcinogenic and related hydrocarbons, for the determination of fluorescence in liquid solution, and for the photography of the fluorescence spectra of these hydrocarbons in solution and in the solid state. Solid solutions (0.1 per cent.) of naphthacene in 3:4-benzpyrene, 20-methylcholanthrene, 9:10-dimethyl-1:2-benzanthracene, 1:2-benzanthracene, or in anthracene show fluorescence bands, which differ from those of either component and appear to be characteristic of the fluorescence of naphthacene in solid hydrocarbon solutions. The solid hydrocarbons and their solid solutions with naphthacene lose their ability to fluoresce on fusion in air or in a vacuum and regain it on resolidification. 3:4-Benzpyrene, when heated in liquid solution to its melting point retains its fluorescence. Naphthacene does not inhibit the fluorescence of liquid solutions of the hydrocarbons. C.

**Photo-electric Photometer: Instrument Setting Errors.** R. H. Hamilton. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 123-126. Mathematical and experimental proofs show that errors in settings of the galvanometer for zero and for incident illumination, and errors in reading the galvanometer deflection for transmitted light, produce high relative errors when a photo-electric photometer is used with solutions of high or of low absorption. For maximum accuracy, conditions should be so chosen that readings of transmitted illumination fall on the central portion of the scale. C.

**Trichromatic and Dichromatic Vision: Theory.** F. H. G. Pitt. *Proc. Roy. Soc.*, 1944, 132 B, 101-117. It is shown that if the dichromatic isocolour lines, plotted on any colour diagram of the usual type, are extended, they will either meet at a point which will represent a missing fundamental sensation, or they will be parallel to a line joining the points representing the two fundamental sensations which are fused. By using these properties it is further shown that protanopia is caused by the absence of the  $R'$  sensation, that tritanopia is caused by the absence of the  $B'$  sensations and that deuteranopia is caused by the  $R'$  and  $G'$  sensations being identical. The  $B'$  and  $R'$  points determined by these measurements and the  $G'$  point as determined by Walters, but slightly modified to suit the particular requirements set by the line  $R'G'$ , have been used to calculate the fundamental sensation curves. Luminosity, colour-mixture, and hue-discrimination data for both dichromatic and trichromatic observers, and to a less extent trichromatic adaptation and saturation data, are satisfactorily explained in terms of these response curves; such an explanation leads to the conclusion that the Young-Helmholtz theory of colour vision is fundamentally correct. The essential difference between the  $B'$  sensation and the  $G'$  and  $R'$  sensations is stressed. C.

**Circular-arc Cam with Flat Follower: Displacement, Velocity and Acceleration Curves.** W. Marsh. *Engineering*, 1944, 157, 362. A method of drawing curves showing the displacement, velocity and acceleration of the follower of a circular-arc cam with flat follower is explained, and acceleration and velocity curves are shown for the case of a circular-arc cam giving a rise and fall of 1 in. during 180° rotation. C.

**Plastics: Dielectric Properties and Use for Insulation.** T. Hazen. *Plastics Resins Ind.*, 1943, 1, May, 11 (through Mark & Proskauer's *Resins, Rubbers, Plastics, Abstr.*, 1943, A:814). The dielectric properties of polystyrene, phenolic cambric varnishes, resin-like or resin-containing liquid dielectrics, and

vinyl resins are discussed and some characteristic curves are given. Applications of these materials for electrical insulation are mentioned and limitations are indicated. C.

**Chain Polymers: X-Ray Structure.** C. S. Fuller and W. O. Baker. *J. Chem. Educ.*, 1943, 20, 3-10 (through *Brit. Chem. Abstr.*, 1944, A1, 5). X-Ray fibre patterns of polyethylene, polyisobutylene, polyvinyl alcohol, polyvinylidene chloride, several polyesters and polyamides, and cellulose triacetate are reproduced and discussed. C.

**Mass-produced Articles: Sampling for Quality Control.** W. Bartky. *Ann. Math. Statistics*, 1943, 14, 363-377. A multiple sampling procedure is proposed for controlling the acceptance of batches according to the percentage of defective units, in which a first sample is inspected, and on the basis of the results, either the batch is accepted, or it is rejected, or a second sample is taken. If a second sample is taken the procedure is then repeated on this and as many subsequent samples as are necessary to justify either acceptance or rejection of the batch. A few criteria for assessing the results of each sample are chosen and for these formulae are worked out for determining (a) the probabilities of accepting and rejecting various batches, and (b) the number of units tested per batch. C.

**Sodium Hypochlorite Solution: Use as Titrimetric Reagent.** N. I. Goldstone and M. B. Jacobs. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 206-207. Standard sodium hypochlorite solution is recommended as a general titrimetric reagent for micro-analytical work. The preparation of the solution and a procedure for standardisation with standard sodium arsenite or potassium antimonyl tartrate solution are described. The hypochlorite solution must be made with sufficient excess of sodium hydroxide so that the pH is about 12.5 and must be stored in brown, glass-stoppered bottles. Under these conditions, sodium hypochlorite solution is remarkably stable and compares favourably with other titrimetric reagents. Its advantages, compared with potassium bromate, for the micro-determination of antimony and arsenic are pointed out. C.

**Aluminium: Colorimetric Determination; Precision and Accuracy.** A. L. Olsen, E. A. Gee and V. McLendon. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 169-172. A colorimetric determination of Al (as  $\text{Al}_2\text{O}_3$ ) is described that involves the formation of the red complex with aurin tricarboxylic acid. The factors influencing colour intensities have been investigated and precision and accuracy studies have been made on typical analytical data. The average precision, measured by the average deviation of the single results from the mean, is about 1 per cent., whilst the over-all accuracy is about 1 to 3 per cent. C.

**Manganese: Determination.** J. I. Watters and I. M. Kolthoff. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 187-189. Details are given of experimental studies which show that vanadyl, vanadate, ceric, cerous, and chromic ions are quantitatively precipitated with an excess of ferric iron when hydrous ferric oxide is precipitated by pyridine. Chromate, however, divides between the precipitate and filtrate. The loss of chromium in this way can be prevented by the addition of a little sodium bisulphite solution. Manganous and ferrous ions remain quantitatively in the filtrate. The use of pyridine is advantageous in separating the interfering metals V, Cr, Ce, and a large excess of Fe from Mn prior to the polarographic determination of Mn as tri-dihydrogen pyrophosphatomanganate. C.

**Zinc: Determination.** P. J. Elving and J. C. Lamkin. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 194-198. A rapid control method for the determination of zinc in alloys comprises precipitation of Zn as the oxalate in aqueous acetic acid solution, centrifugal separation of the precipitate, dissolution in sulphuric acid, and titration of the oxalic acid with standard permanganate. Interfering effects of other elements and their removal are briefly discussed. Applications of the method to the determination of zinc in various alloys and concentrates are described. C.

**Phthalic Anhydride: Determination in Oil-modified Alkyd Resins.** C. D. Doyle. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 200. In a modification of the Kappelmeier method, the alcohol of crystallisation is removed from the precipitate obtained on hydrolysis of the alkyd resin with alcoholic potassium hydroxide by heating at 210° C. for one hour and the dipotassium phthalate is weighed. Results obtained for various resins by the standard and modified

procedures are compared. The data show that the modified procedure is applicable also to alkyd resins complicated by maleic anhydride or fumaric acid. C.

**Phthalic Anhydride: Determination in Oil-modified Alkyd Resins.** A. I. Goldberg. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 198-200. The Kappelmeier method for the determination of phthalic anhydride in oil-modified alkyd resins involves hydrolysis of the resin with alcoholic potash, which gives a precipitate of potassium phthalate containing one mole of alcohol of crystallisation. Disadvantages of the standard procedure are pointed out and modifications are suggested. Anhydrous potassium phthalate is recommended as the weighing form instead of the alcoholate. A simplified saponification procedure is described. The adverse effect of water and its elimination are discussed. A method is described for the titration of the dipotassium phthalate with perchloric acid in glacial acetic acid. C.

**Plant Samples: Grinding; Risk of Mineral Contamination.** S. L. Hood, R. Q. Parks and C. Hurwitz. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 202-205. An account is given of an investigation of the contamination of plant tissues resulting from grinding in common grinding mills and of the effects of the method of grinding, type of plant material, duration of grinding, and size of plant sample. Grinding in a Wiley mill and a hammer mill led to contamination by Fe and Cu. Jar mill grinding with flint balls resulted in contamination with Fe, Zn, Cu, Co and Na. The use of porcelain or Mullite balls during jar mill grinding gave rise to appreciable contamination with Fe, Zn, Cu, Co, Na, and in some cases Ca, S and P. Hand grinding with a mortar and pestle resulted in no appreciable contamination with Fe, Zn, Cu, B, Co, Mn, Mo, Ca, Na, Mg, P, S or K. Large increases in contamination with Zn, Fe, Cu, Co and Na resulted from decrease in size of plant samples ground in a jar mill using flint pebbles. For the types of mills studied, less contamination arose in the grinding of vetch seed than in the grinding of oat grain. The conclusion is drawn that marked errors would be involved in using the common mills for grinding plant tissue for general or extensive micro-analysis. C.

**Cellulose: Degradation with Inorganic Acids in the Presence of Acetic Acid.** A. Marschall and H. Stauch. *J. makromol. Chem.*, 1943, 1, 55-75 (through *Chem. Abstr.*, 1944, 38, 1353<sup>s</sup>). The raw materials for this investigation included two cotton linters [degree of polymerisation (D.P.) 863 and 1780], a rayon pulp (88 per cent.  $\alpha$ -cellulose, D.P. 897) and a refined pulp (96 per cent.  $\alpha$ -cellulose, D.P. 1080). These were treated with acetic acid containing 1, 2 and 4 per cent. sulphuric acid or 2 per cent. perchloric acid at 30 or 40° for 2, 4, 15 and 72 hours and examined for D.P. (nitrate method), alkali solubility, formic acid-zinc chloride solubility and  $\text{HSO}_3$  content. The combined  $\text{HSO}_3$  content was a maximum after the 2-hour period and after 72 hours had decreased about 25 per cent. The alkali solubility (compared at the same D.P.) did not increase in proportion with the sulphuric acid concentration and was greater for the sulphuric than the perchloric acid treatment (especially for the linters of lower D.P.). Alkali-solubility data are given also for aqueous acid (2N. sulphuric, 2N. perchloric and N. hydrochloric acid) treatment; in this case the perchloric acid gave higher solubility values (excepting for the linters with D.P. 1780). The yields of cellulose with 1 and 4 per cent. sulphuric acid in acetic acid were 87-95 per cent. after 2 hours and 62-76 per cent. after 72 hours; with the aqueous acids or with acetic acid alone, the yields were about 97 per cent. These differences are explained by the change in fibrous structure in sulphuric acid-acetate acid, the fibres being degraded to fragments (illustrated by photo-micrographs). Drying of the sulphuric acid-acetic acid treated material decreased the alkali solubility. A study is reported also of the glucose number of the above cellulose preparations, determined by the reversible methylene blue method; the  $\text{HSO}_3$  could not be determined by this method. C.

**Cellulose: Structure.** F. T. Peirce. *Nature*, 1944, 153, 586-587. The crystalline structure of cellulose suggested by Meyer and Misch and a molecular structure based on the view of Cox and co-workers that the five carbon atoms of the pyranose ring are nearly co-planar are critically discussed. A form is suggested in which the pyranose rings are turned from the plane of similarly orientated

chains towards the plane containing chains of alternating sense. Molecular structures assigned to native and regenerated cellulose are shown. C.

**Nitrocellulose and Vinylite Resin: Mechanism of Solution.** A. K. Doolittle. *Ind. Eng. Chem.*, 1944, **36**, 239-244. The action of solvents on macromolecular substances is studied, and threshold concentration and viscosity data are given for nitrocellulose in various solvent-diluent mixtures and for Vinylite resin in mixtures of nitroparaffins with *n*-butanol or *n*-heptane. It is suggested that two principal equilibria are simultaneously operative in the solution of resinous substances—solvation-desolvation and aggregation-disaggregation. The rate of desolvation is substantially fixed at constant temperature, but the rate of solvation is a function principally of solvent concentration. The threshold concentration required to initiate the solution process diminishes to a constant minimum value in ascending a homologous series of solvents. This minimum value, called "class threshold concentration," is independent of the diluent and therefore serves as an absolute comparison of different classes of solvents for a given resinous substance. The aggregation-disaggregation equilibrium of the solute macromolecules depends on the solvation-desolvation equilibrium, since disaggregation results when the "active centres" are solvated. In fluid solutions the extent of aggregation of the solute macromolecules increases linearly with decrease in solvent concentration, but as the solvent concentration approaches the threshold value, desolvation permits aggregation at multiple points of contact. The result is either gelation or precipitation. In film formation, the high viscosity, resulting from aggregation by means of gradual two- and three-dimensional growth as the resin desolvates during evaporation of the solvent, obstructs the tendency of the macromolecules to unite with one another at the maximum number of points of contact. A rather extended structure results. Plasticization prevents complete desolvation of the resin, and therefore diminishes the opportunity for the macromolecules to unite with one another at multiple points of contact. In this manner a less rigid structure is produced. C.

**Starch Conversion Products: Refractive Index.** J. E. Cleland, J. W. Evans, E. E. Fauser and W. R. Fetzer. *Ind. Eng. Chem., Anal. Edn.*, 1944, **16**, 161-165. A procedure for the determination of the refractive index of starch conversion products is described and results are presented for corn syrups and corn sugar syrups made by the simple hydrolysis of starch by acid. The refractive index of these products decreases with increasing dextrose equivalent. The effect of ash (sodium chloride) is to increase the refractive index. The decrease of refractive index with increasing dextrose equivalent is proportional to the increase in dextrose equivalent if the ash content of the products is also proportional to the dextrose equivalent. The temperature/refractive index relationship is linear within the range 18° to 45° C. when the concentration exceeds 14 per cent. of dry substance and within the limits of precision of a four-place instrument. Tables are presented covering the refractive index/dry substance relationship for commercial starch conversion products and refractive index/commercial Baumé for typical commercial products of different dextrose equivalents. C.

**Dipyrromethene and Triphenylmethane Dyes: Structure.** K. J. Brunings and A. H. Corwin. *J. Amer. Chem. Soc.*, 1944, **66**, 337-342. A consideration of various derivatives leads to the following conclusions: (1) The structure of the dipyrromethenes is profoundly influenced by the substituents on the pyrrole rings; (2) the position of the substituents is critical; (3) substitution of carboxy groups increases stability of the colourless covalent form of the methene, but alkyl substitution favours the ionic salt structure; (4) alkyl substitution on the pyrrole nitrogens results in steric interference causing a decrease in the stability of the ionic coplanar form and is, therefore, opposite to the effect predicted on the basis of the electrical effect of alkyl groups. The preparation of several new dipyrromethene carbinols, and of two colourless dipyrromethyl bromides which are analogous in structure and behaviour to triphenylmethyl bromide, is reported. It is shown that steric interference of hydrogens or substituents ortho to the bridge carbon atom exerts a strong influence on the structure of both the triphenyl and dipyrromethane dyes. The present observations on the dipyrromethenes and previously established data on the triphenylmethane series are correlated on the basis of a common electronic interpretation.

Certain differences in behaviour are explained by a comparison of the structural geometry of the two dye systems. C.

**High Polymers: Chain Configuration; Statistical Theory.** P. J. Flory and J. Rehner, Jr. *Ann. N.Y. Acad. Sci.*, 1943, **44**, 419-429 (through *Chem. Abstr.*, 1944, **38**, 1162<sup>9</sup>). The theory is examined in the light of more recent knowledge about the potential hindering rotation about single C—C bonds. It is shown that the form of the distribution function of possible distances between chain ends is not changed by the introduction of this potential. The average distance, however, is increased. Various methods for calculating elastic moduli of flexible networks are discussed. The authors' treatment leads to a stress-strain curve identical with the one derived by Wall. Swelling phenomena in such networks are considered on the basis of the authors' theory. C.

**Lyophil Protein Evaporation Apparatus.** D. H. Campbell and D. Pressman. *Science*, 1944, **99**, 285-286. A simplified lyophil apparatus which has proved satisfactory for small-scale laboratory work is described and shown in diagrams. Solutions to be dried are placed in pear-shaped flasks which are placed in a dry ice freezing mixture until the contents are frozen solid. The flasks are then connected to a condenser which is cooled with a freezing mixture of dry ice and ethyl cellosolve, and the assembly is evacuated. The temperature inside the flasks depends upon the rate of evaporation, and under the described conditions is well below freezing until all the water has been removed. The rate of evaporation may be increased by blowing a current of air over the flasks or immersing them in cold water. Materials being dried from very dilute solutions have a tendency to be carried out of the flask with the current of water vapour; this may be prevented without causing any appreciable decrease in evaporation by placing a gauze screen over the opening of the flask. A curve is given showing the amount of water remaining as a function of time for 150 g. of distilled water distributed equally among three flasks. Complete dryness was achieved in about 5 hours. Water is evaporated from protein solutions at a comparable rate, depending to some extent on the hygroscopic nature of the material. C.

**Wheat Flour Proteins: Sulphydryl Group Content.** H. S. Myers and E. B. Working. *Cereal Chemistry*, 1944, **21**, 32-37. Nitroprusside and ferricyanide tests for sulphydryl groups were made on the various fractions of wheat flour before and after denaturation. No indications were obtained of the presence of either reactive or unreactive sulphydryl groups in the gluten proteins. There appeared to be no free sulphydryl groups in the soluble protein fraction of flour. Definite indications were, however, obtained of the presence of unreactive sulphydryl groups which were liberated on denaturation of these soluble proteins. The presence of sulphydryl groups in the lipid fraction was confirmed. C.

**Adsorbed Phases: Condensation and Supersaturation.** H. M. Cassel. *J. Amer. Phys.*, 1944, **12**, 115-116. It is pointed out that in the derivation of Langmuir's adsorption isotherm the interaction of neighbouring adatoms has been neglected. Consequently, the equation of state of the monolayer corresponds to that of a compressed gas above its critical point. The treatment of multilayers in the adsorption of vapours is considered, and it is shown that an expression for the film pressure derived from the Emmett-Brunauer-Teller adsorption isotherm leads to the conclusion that the surface tension of the finally built-up, presumably liquid film would be negative. This result is attributed to the disregard of lateral cohesion in the design of the film model. In considering the mutual attraction of adatoms, cluster formation and phase transitions can be anticipated. Accordingly, the adsorption isotherm of a vapour must show a discontinuity, of course also in the case of perfect wettability. Then, depending on the free energy of nucleus condensation, metastable mono- or multilayers should be observed. It is very likely that the hysteresis in capillary condensation represents a supersaturation phenomenon of this kind. C.

**Adsorption Isotherms: Derivation.** W. D. Harkins and G. Jura. *J. Chem. Phys.*, 1944, **12**, 112-113. It is pointed out that the treatment of the adsorption of vapours on the surfaces of solids should not be considered as independent of, but as only a part of a general treatment of, the behaviour of insoluble and adsorbed films on the surfaces of liquids and of solids of all types. Since the

fundamental property of a surface, which determines the adsorption of a vapour or the spreading of an insoluble film, is the free energy of the surface itself, this quantity should be the fundamental basis of the treatment of this subject. Equations which give the pressure-area relations of insoluble oil films on water should apply also to adsorbed films on solids or on liquids. From these considerations a new basis has been adopted for the determination of equations for adsorption isotherms. This consists of considering as impractical attempts to develop a general equation for an entire adsorption isotherm, and in the determination of a single equation for each of the known phases which exist in oil films on water. A later step is to apply these equations to the pressure-area relations exhibited by isotherms for films on solids. In some cases one equation fits two different phases, but with very different values of the constants. It is found that the equations for insoluble films on water fit equally well for adsorbed films on solids. When the equation for a condensed film on water is applied to films on solids it is often found that the plot obtained exhibits two straight lines such as to indicate the existence in the film on the solid of two condensed phases with a second-order transition, and thus an absence of a latent heat, between them. The transition between the intermediate and the condensed film may be considered as of the third order. Examples of this are found in films of propyl alcohol on barium sulphate or anatase, and of nitrogen on certain catalysts used in the petroleum industry, or on certain charcoals. The only previously recognised phase on solids is the gaseous film. C.

**Cellulosic Films: Shrinkage on Precipitation.** F. H. Müller. *Kolloid Z.*, 1943, 103, 144-145 (through *Chem. Abstr.*, 1944, 38, 1161<sup>1</sup>). The author describes shrinkage and other allied phenomena observed when films of polystyrene, polyisobutylene and cellulose derivatives are cast from solutions of these materials on to glass or water. C.

**Films on Solids: Expanded and Intermediate Phases.** G. Jura and W. D. Harkins. *J. Chem. Phys.*, 1944, 12, 114. From a study of adsorbed films of butane on porous solids (catalysts) at 0° C. it is shown that the equations developed for insoluble monolayers on water in the liquid expanded and intermediate phases are valid for certain films adsorbed on the surfaces of non-porous and porous solids. From this evidence the conclusion is reached that these two non-condensed phases exist in films on the surfaces of solids as well as on liquids. C.

**Liquid Expanded and Intermediate<sup>ac</sup> Monolayers on Water: Pressure-Area Relations.** G. Jura and W. D. Harkins. *J. Chem. Phys.*, 1944, 12, 113-114. Equations for the pressure-area relations of liquid expanded and intermediate films of insoluble materials on aqueous sub-phases are obtained by integration of the equations for compressibility. The equations obtained represent experimental data adequately. Curves are given showing the application of the equations to the liquid expanded and intermediate films of pentadecylic acid at 27.5° C. on water. C.

**Paraffin Chain Salt Solutions: Surface Activity; Effect of Electrolytes.** R. G. Aickin and R. C. Palmer. *Trans. Faraday Soc.*, 1944, 40, 116-120. The addition of electrolytes to solutions of paraffin chain salts increases the surface activity of these solutions, and the effect is due almost entirely to the ions of opposite sign to the surface active species. A theory is developed which takes into account the charge and size of the ions and explains the difference in the effect of various added ions of the same valency on the surface activity of paraffin chain salts. C.

**Elastic Structures: Solution of Stress Problems; Lattice Analogy.** D. McHenry. *J. Instn. Civ. Engrs.*, 1943, 21, 59-82 (through *Sci. Abstr.*, 1944, 47 A, 32). The author describes a computation method for the numerical solution of almost any type of two-dimensional stress problem involving elastic materials. The method is one of successive approximation. It is derived in two ways, one employing Taylor's theorem, and the other by the lattice analogy in which each small element of the section is replaced by a braced square frame composed of six elastic members which have certain defined properties. The solution of the lattice is exemplified by the case of a plate stressed

by forces acting in its plane; determination of the stresses follows. Hints are given on the successful application of the method. C.

**High Polymers: Elasticity and Flow.** R. Simha. *Ann. N.Y. Acad. Sci.*, 1943, 44, 297-312 (through *Sci. Abstr.*, 1944, 47 A, 39). This paper deals with rate phenomena in amorphous materials in general, and particularly in amorphous high polymers, when one of the variables, shearing stress, volume, pressure or temperature, changes rapidly. The molecular mechanisms, responsible for the large elastic deformations in rubber-like materials are briefly examined. The case of elastic deformation in high polymers is explored. With certain simplifications, a statistical treatment will afford numerical results for the equilibrium value of the high elastic component of deformation. Rubber-like elasticity accompanies the existence of relatively free rotation within a chain as determined by the interactions along the main chain skeleton and by the nature and size of the side groups. Distinctions between rubber-like materials (polyisoprene, neoprene, and polyisobutylene) are examined. C.

**Plastic Materials: Shear Strength.** R. T. Schwartz and E. Dugger, Jr. *Modern Plastics*, 1944, 21, No. 7, 117-121, 164-166. A report is given of determinations of the shear strength at room temperature of various thermoplastic and thermosetting plastic materials. Two standard procedures were used, consisting of testing in double shear (1) rectangular specimens from sheets of  $\frac{1}{16}$ ,  $\frac{1}{8}$  and  $\frac{1}{4}$ -inch thickness, employing a Johnson-type shear jig with compressive loading, and (2) cylindrical specimens from sheets of  $\frac{1}{8}$ -in. or greater thickness, using a 3-plate-type shear jig with tensile loading. The results are tabulated and discussed. The average ultimate shear strength of the thermosetting plastic materials ranged from 4,400 lb. per sq. inch for transparent, unfilled allyl-derivative plastic material to about 12,000 to 18,000 lb. per sq. in. for the various laminated phenolic paper- and fabric-base plastic materials. The shear strength of the thermoplastic materials ranged from 200 lb. per sq. in. for a cellulose acetate material to 10,000 lb. per sq. in. for polyvinyl chloride-acetate. Shear values of the thermosetting plastics obtained on sheets of different thicknesses in the Johnson jig were comparable and were in turn comparable with the values obtained on the 3-plate jig. With the Johnson jig, higher shear values were obtained with a decrease in thickness of the thermoplastic materials. The higher shear values are considered nearer the actual shear strength. The values obtained on material  $\frac{1}{8}$ -in. thick were comparable with those obtained with the 3-plate jig. On fracturing, most of the filled materials showed relatively smooth separation planes whereas most of the unfilled materials showed jagged irregular surfaces. Shear strength was higher edge-wise than flat-wise for a phenolic laminate prepared with high-strength paper base, though no significant difference was observed for a phenolic-resin-impregnated laminated compressed maple. Shear strength parallel to the laminations was much lower than for other directions for laminated materials. There was no specific correlation between shear strength and compressive or tensile strength. C.

**High-molecular Substances: Vibratory Grinding.** E. Steurer. *Chem. Tech.*, 1943, 16, 1-3 (through *Chem. Abstr.*, 1944, 38, 1152<sup>4</sup>). The principal mechanical and chemical effects, the relation between the energy developed in the mill and the molecular energy of the substance, the energy balance, and the atomic energy and compression strain are discussed. Electron and Röntgen photographs are given in the original paper. C.

**Pigments: Mounting for Electron Microscopy.** M. L. Fuller, D. G. Brubaker and R. W. Berger. *J. Appl. Physics*, 1944, 15, 201. The following method for the preparation of pigment mounts has been found successful with a wide variety of zinc oxide pigments, leaded zinc oxide, titanium dioxide, zinc sulphide and lithopone. Approximately 0.01 g. of the pigment is milled on a glass plate with a glass muller using 3 drops of a 1 per cent. solution of poppy-seed oil in amyl acetate. The mulling is continued until the paste is nearly dry. To the paste are added 3 drops of a 2 per cent. solution of nitrocellulose in amyl acetate. This is milled until the solvent has evaporated. About 8 drops of a 2 per cent. solution of nitrocellulose in isopropyl acetate are added and milled for a few seconds (long enough to put the pigment in suspension), and 1 drop of this is allowed to spread on the surface of a saturated solution of salt. A portion of the resulting thin film is removed on a glass slide, refloated on

water to wash away the salt, and then attached to the standard 200-mesh screen disk. The individual steps are briefly discussed and the advantages of this method are pointed out. C.

**Shewhart Quality Control Chart: Application.** W. E. Deming. *Mechanical Engineering*, 1944, 66, 173-177. The effects of the use of the statistical method in quality control are outlined and the underlying principles are explained. The two kinds of mistakes occasionally made in quality-control programmes are: (1) Looking for an assignable cause of variation or increasing the amount of inspection, when the variations in quality are only random. (2) Failing to look for an assignable cause of variation or failing to increase the amount of inspection, when an assignable cause actually does exist. The Shewhart control chart has been designed to answer the question, when to look for an assignable cause, by striking an economic balance between these two kinds of mistakes. The use of this control chart is explained. It is pointed out that the statistical work can only be effective if it is accompanied by good engineering control of the process, training of the personnel, frequent review of sampling and test procedures with careful checks on actual performance, and frequent calibration of instruments and gauges. C.

**Halogens: Action on Wool. I. Factors Influencing the Amount of Halogen Adsorbed from Solutions in Carbon Tetrachloride.** C. S. Whewell and A. Selim. *J. Soc. Chem. Ind.*, 1944, 63, 121-123. The amount of chlorine adsorbed by wool from solutions of the gas in carbon tetrachloride depends on the duration of treatment, concentration, bulk ratio, temperature, regain, type of wool and any chemical treatment to which it may have been subjected. Deaminating reagents caused a much greater decrease in the adsorption than those which attack the disulphide links. Human hair adsorbed less chlorine than wool; differences between root and tip wools were small; differences between untreated and sodium sulphide-treated wools were insignificant; hydrogen peroxide-treated wool adsorbed less chlorine than untreated wool. W.

**Cystine: Rate of Liberation from Proteins by Acid Hydrolysis.** W. C. Hess and M. X. Sullivan. *Archives of Biochem.*, 1943, 3, 53-60. Six proteins (wool, finger nail clippings, lactalbumin, gliadin, edestin and  $\alpha$ -globulin of the lima bean) were hydrolysed by hydrochloric acid, hydrochloric acid-formic acid and hydriodic acid containing 1 per cent. hypophosphorous acid, for periods from 15 min. to 24 hr., and the cystine liberated estimated by the Sullivan and Okuda methods. The maximum values by all 3 hydrolysis procedures for each protein were practically identical. There are indications that the sulphur of wool is tied in more than one form; this possibility will be investigated. Hydrolysis with 5 and 10 per cent. hydrochloric acid indicates that the liberation of cystine from wool is a second order reaction. W.

## 10—ECONOMICS

**Wool and Synthetic Fibres.** P. Larose. *Wool Rec.*, 1944, 65, 547. Many arguments in favour of wool show a misunderstanding of its desirable characteristics, especially of its resiliency, and advertising will be ineffective unless it is based on a proper programme of research. W.

**Wool and Synthetic Fibres.** (1) H. Schofield. (2) J. Bolland. *Wool Rec.*, 1944, 65, 587. Reference is made to Larose's statements (see preceding *Abs.*), (1) It is extremely unlikely that for purposes of warmth wool will be replaced by any synthetic production. (2) Judging from "over-the-counter" sales, and from an example of research into new methods of improving the handle and durability of wool fabrics, the wool trade cannot be accused of complacency in the face of competition from synthetic fibres. W.

**British Patent System.** Chartered Institute of Patent Agents. *Engineering*, 1944, 157, 356. It is pointed out that the patent system is based on the recognition of a temporary proprietary right in the technical creations of the individual mind. Criticisms of the system and suggested modifications are discussed. Provisions against abuses are shown to be adequate and cases of alleged abuse rare. The addition of a provision designed to ensure that monopoly rights held in Great Britain shall not be a hindrance to the full creation and satisfaction of the demand for a patented article in export markets is recommended.

The proposal for the universal adoption of some general system of issuing licences under all patents as a right open to all persons interested in the manufacture of the patented invention ("licences of right") is subjected to a critical study and the conclusion is reached that such a system of compulsory licensing is inadvisable on the ground that it would retard the progress of invention for the following main reasons: (1) enterprise in developing and exploiting inventions would suffer on account of uncertainty and insecurity; (2) research by individual firms would be restricted; and (3) the practice of secret working of inventions would develop wherever possible, thus removing the incentive to scientific progress which is derived from publicity and wide circulation of information. It is suggested, however, that the principle of "licences of right" should operate to a full or partial extent in relation to patentable inventions resulting from State-financed research. It is also suggested that, in regard to the patenting of inventions resulting from State-financed or State-aided research, it is in the national interest to consider whether there should be established under the general supervision of the State, a body which might procure patents in other countries for the protection, to the national benefit, of important inventions. C.

**Textile Wholesale Prices, April, 1944.** *Bd. Trade J.*, 1944, 150, 177. The wholesale price index numbers for April are Cotton 150·1, Wool 183·8, Other textiles 134·1 (1930=100). C.

**Cotton: World Supply and Consumption.** *Rayon Organon*, 1943, 14, 163-165. Tables are given showing the world supply and consumption of American and all cotton in the period 1920-1943. The American production in 1943 is estimated at 11,450,000 bales, making with the carry-over a total domestic supply of 22,019,000 bales of American cotton, 9 per cent. lower than the peak of 24,374,000 bales in 1939 and 5 per cent. lower than the 1942 supply of 23,138,000 bales. The mill consumption of native cotton in the United States for the 1942 season was estimated at 10,930,000 bales or slightly lower than the peak year 1941, but 62 per cent. higher than the pre-war season 1938-39. The carry-over of all cotton on August 1st, 1943, amounted to 10,657,000 bales, and that in other countries to 13,257,000 bales. For the season ending July 31, 1943, the world production of all cotton was estimated at 26,483,000 bales, making a total supply for that season of 49,003,000 bales. During the period, United States mill consumption aggregated 11,100,000 bales, whilst mill consumption in other countries declined to a figure of 13,750,000 bales, making a total world consumption of all cotton of 24,850,000 bales, or 3 per cent. lower than the previous season and 13 per cent. below the pre-war season of 1938-39. C.

**Hosiery: American Production in 1942.** *Rayon Organon*, 1943, 14, 61-66. A table is given showing productions in the United States of the various types of hosiery in 1942 and 1941. The 1942 total of all types amounted to 147,902,058 dozen pairs, compared with 149,968,435 in 1941. Production of women's full-fashioned hosiery declined from 41,818,722 dozen pairs in 1941 to 35,082,296 in 1942. In the first half of 1942, rayon hosiery accounted for 54·5 per cent. of the total women's full-fashioned output, whilst in the second half of the year the rayon share increased to 88·3 per cent. The 1942 output of all types of women's seamless hosiery was about 3 per cent. below that of 1941. Women's rayon seamless hosiery production in 1942 at 8,088,000 dozen pairs represented 60·6 per cent. of the total production. Higher production levels in 1942 were achieved in men's half hose and slacks, socks, cotton and woollen bundle goods and anklets. Production declines occurred in athletic socks, ribbed goods and children's and infants' wear. Details are given of the Office of Price Administration price ceiling order on women's full-fashioned and seamless rayon hosiery and the War Production Board hosiery conservation order. C.

**Industrial Products: Distribution.** F. B. Turck and W. E. Hill. *Mechanical Engineering*, 1944, 66, 183-191. Twelve scientific distribution principles, namely, customer development, corporate accounts, stabilizing, demand for capital goods, marketing budgets, distribution planning, pricing policy, distribution administration, diversification, product development, market development, sales organisation and foreign distribution, are discussed and illustrated by the actual experience of leading industrial companies. C.

**Lancashire Cotton Industry: Structure.** Cotton Board. *Textile Manufacturer*, 1944, 70, 147, 157. The average spinning mill in Lancashire has about 85,000 mule-equivalent spindles, compared with 35,000 in Germany, 20,000 in Italy, 70,000 in the northern United States and 30,000 in the southern States, and 40,000 in Japan. More than 85 per cent. of British spindles are in mills with more than 60,000 spindles each, and 10 firms alone control 40 per cent. of the spindles. In weaving, however, the ten large firms control only 10 per cent. of the looms. In the finishing section the ten large "converters" had in 1939-40 an annual turnover of 25 to 80 million yards and controlled one-fifth of the export trade. The unique feature of the British industry is the relatively small extent of "vertical" organization. Combined spinning and weaving concerns control only 18 per cent. of the spindles and looms in Lancashire as against 40 per cent. in Germany. Further, the ten large converters responsible for 15 per cent. of their trade control only 5 per cent. of the looms. In the United States, combined spinning and weaving firms control 80 per cent. of the spindles, nearly all the looms, and half of the finishing trade. C.

**Lancashire Weaving Industry: Reconstruction.** F. W. Lowcock. *Textile Manufacturer*, 1944, 70, 144-145. Suggestions are made for the improvement of the cotton and rayon weaving industry, by attention to loom design and conditions of employment, and by financial aid for plant renewal and export of cloth. A Reconstruction Committee to control the industry is advocated. C.

**Silk: Dwindling Application.** A. D. Kelly. *Rayon Textile Monthly*, 1944, 25, 73-75. In 1920 raw silk sold in the United States for more than \$18 per lb. and georgette throwing was done at \$5 per lb. In the 1930's raw silk fell to \$1 per lb. In the peak year (1929) the weaving trade consumed about 32,000 bales per month and the fully-fashioned hosiery trade about 19,000 bales, or about 37 per cent. of the total. In 1941, the hosiery trade consumed about 18,000 bales out of a total of 23,000 bales per month. It is considered that real silk will not recover from the introduction of nylon for hosiery. Other replacements of silk include rayon in hosiery, ribbons, neckties and velvets, nylon for parachutes, and chemically treated cotton or spun rayon for artillery powder bags. C.

**Rayon: World Production.** *Rayon Organon*, 1943, 14, 169-171. World rayon production increased from 2,227,500,000 lb. in 1939 to 3,472,900,000 lb. in 1942, a gain of 56 per cent. The two countries contributing most to this increase were Germany with a gain of 480,000,000 lb. and the United States with an increase of 252,700,000 lb. Of the 1942 world total production, 1,447,200,000 lb. was filament yarn (an increase of 26 per cent. on 1941) and 2,025,700,000 lb. was staple fibre (87 per cent. increase). Production of both filament yarn and staple fibre in Great Britain showed a decline. For filament rayon yarn manufacture countries ranked for both 1939 and 1942 as follows: United States, Japan, Germany, Italy and Great Britain, but the ranking for staple fibre production was Germany, Japan, Italy, Great Britain and the United States for 1939, and Germany, Japan, Italy, United States, France and Great Britain for 1942. When arranged according to total rayon production for 1942, Germany leads with 1,100,000,000 lb. (32 per cent. of the total), Japan follows with 700,000,000 lb. (20 per cent.) and the United States with 632,600,000 lb. (18 per cent.). C.

**Textile Fibres: Consumption in United States, 1942.** *Rayon Organon*, 1943, 14, 30-32. Tables and charts are given showing the consumption of cotton, wool, rayon and silk in the United States in the years 1920-1942. The consumption of raw cotton in 1942 reached a new record of 5,616,600,000 lb., an increase of 8 per cent. above the previous record of 5,208,500,000 lb. in 1941. Scoured wool consumption in 1942 at about 610,000,000 lb. was 7 per cent. below the record level of 652,200,000 lb. used in 1941. Rayon consumption (continuous filament plus staple fibre) in 1942 at 620,600,000 lb. passed the record 591,700,000 lb. of the previous year by 5 per cent. and was more than double the figure for 1937. C.

**Textile Fibres: Production and Applications.** Cotton Textile Institute, U.S.A. *Rayon Textile Monthly*, 1944, 25, 13-14, 67-68, 119-120, 172-174. A report is given of a conference on the respective fields of application of the various fibres (the "battle of the fibres"). (1) S. B. Hunt discusses statistics

of production and consumption. The amounts consumed in the United States were, in millions of lb.:—

	1920	%	1930	%	1940	%	1943	%
Cotton (raw) ...	2,828	(88·9)	2,610	(85·0)	3,962	(81·0)	5,455	(80·8)
Rayon (all types)	9	(0·3)	119	(3·9)	482	(9·9)	643	(9·5)
Wool (scoured) .	314	(9·9)	263	(8·6)	411	(8·4)	652	(9·7)
Silk (raw) ...	29	(0·9)	76	(2·5)	36	(0·7)	—	—

The average price of cotton was 34 cents per lb. in 1920, 6 cents in 1932, and is now 21 cents. Wool was 166 cents per lb. in 1920, 66 cents in 1932, and is now 115 cents. Viscose rayon (150 den.) was 600 cents per lb. in 1920, 49 cents in 1938, and is now 55 cents; viscose staple is 24 cents per lb. (2) H. de W. Smith discusses war-time developments of rayon, e.g. for parachutes. (3) F. J. Groten, and (4) A. Hafner refer to Velon cordage and its low inflammability. (5) O. B. Bromley and (6) G. Fuller describe the present position of Aralac (casein) fibre. (7) J. S. Irvine and (8) E. S. Twining describe the properties of spun glass fibre. C.

**Wages: Cost of Living Sliding Scales.** *Planning*, 1944, No. 220, 3-17. The adoption of cost of living sliding scales since about 1916, the method of computing the cost of living index, and various criticisms of the index are discussed. Details are given of the way in which the scales have worked in building and civil engineering, in railway, iron and steel, coal and cotton industries, and in the Civil Service. It is pointed out that during periods of sharply rising prices the pegging of wages to prices will inevitably accelerate the course of the inflation. The workers on sliding scales will then do well, but at the expense of all whose incomes are not adjusted automatically. In the period of falling prices, on the other hand, pegging of wages to prices will mean that deflation is accelerated, as every fall in prices, due to inadequacy in demand, will proportionally reduce wages and consequently demand itself. If wage policy were sufficiently well coordinated between workers and employers and between different industries, it could be arranged that wages should not fall as much as prices during the downswing, and that in return they should not be pushed up so much as would otherwise be the case when prices were once more rising. Such a policy has actually been put into practice in Sweden. From the workers' point of view it would be wrong to peg wages to the cost of living and thus stabilise real wages, if the productivity of the workers was increasing and prices were falling, for this would mean that their share in the product of their labour would be declining. But the use of sliding scales does not preclude the workers from claiming wage increases outside of the scale. If post-war employment policy succeeds in producing a steadily rising national income it is expected that workers in most industries will prefer to rely on their bargaining power rather than on automatic scales. The value of sliding scales varies with the industry. Cost of living calculations will remain of the greatest importance, whether or not an automatic sliding scale is used, as they affect almost all wage negotiations, and all kinds of subsistence allowances, social security payments and minimum wages can most logically be related to a cost of living index. There is an urgent need for an accurate cost of living index, or a number of indices. C.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY, AND EDUCATION

**British Industry: Dependence on Foreign Research.** G. M. Garro-Jones. *Engineer*, 1944, 177, 356. A warning is issued against buying from other countries, under monopolistic conditions, the results of their research activities. This dependence on foreign research was manifest in a number of industries, such as engineering and shoe manufacture, before the war, when certain trades hired at great cost machinery from foreign countries or leased the rights for that plant machinery which they were not allowed in any way to alter. That system made costs rigid and stultified further research. It has been estimated that over half (by value) of the machine tools operating in Birmingham to-day are of American origin. Others of British make are to some extent, no doubt, the subject of patent rights. These imported machine tools have been indispensable to the expansion of war output but their possession is not an unmixed

blessing. The usual life of such tools in a British factory is probably 20 years, whereas in American factories they would be scrapped and superseded by improved plant after about three years. It is suggested that each industry not yet participating in a research association should form a small committee to consider its scientific and technical needs and then discuss the circumstances with the Department of Scientific and Industrial Research. C.

**Scientific Research: Organisation in Great Britain.** (1) *Nature*, 1944, 153, 539. (2) *Parliamentary Debates (Hansard)*, Vol. 399, No. 62, 19/4/1944, column 216-311. A report is given of a recent debate in the House of Commons. The debate revealed a growing recognition of the importance of improving the remuneration, status and conditions of service of the research worker. Tributes were paid to the achievements of research workers in Great Britain and the importance of quality in the research worker was emphasized. It was agreed that fundamental research, on which progress ultimately depends, must be the task of the universities and that there must be much greater expenditure both on fundamental research and on teaching at the universities. It was recommended that industrial research should be directed to the industrial processes which exist in Great Britain, to the discovery of new industries, and especially to the utilization of raw materials which exist at home and in the Colonial Empire. The expansion of research in such fields as animal diseases and nutrition, food and nutrition, soil fertility, and biology, including fisheries, was repeatedly urged. It was suggested that the machinery for giving grants to the universities should be brought more directly under the Office of the Lord President of the Council, who already has the Department of Scientific and Industrial Research under his wing. Other suggestions were that an advisory council for the universities should be formed for the interchange of experience and the prevention of overlapping, that fundamental research should be organized by some sort of parliament of science, and that the Scientific Advisory Committee should be asked to prepare a plan for the development and carrying on of scientific research for a 10-year period. The need for more workers with scientific training in industry, a rapid development of scientific and technical education, closer contact between those engaged in scientific research and those concerned with its practical application, and the discovery of further means of assisting the development and the practical evolution of new industrial ideas was pointed out. Reference was made to the Mellon Institute and its system of industrial fellowships. It was stated that the Government recognizes the need for the establishment of some fund to meet the cost of developing new inventions and of providing facilities for testing new ideas for industry. The best way to meet this need and to fit it in with the work of the research associations is now under examination but Government support for research must be backed by a readiness to use the results of that research and the main responsibility for applied research must continue to fall on industry itself. C.

**Juvenile Textile Workers: Recruitment.** A. Draper. *Silk and Rayon*, 1944, 18, 425-426. A report of a lecture to secondary school pupils on the prospects for employment and training in the textile industries as engineers, executives and supervisors, and testing laboratory workers. C.

**American Textile Research Institute: Establishment of Headquarters at Princeton, N.J.** *Textile Research*, 1944, 14, 66. The Textile Research Institute Inc., has decided to establish headquarters for the prosecution of research and for the training of personnel on the graduate level at Princeton, N.J. The President of Princeton University has declared that the University would afford the opportunity for members of the staff to enrol in graduate courses and proceed to advanced degrees. The programme of study and the research work would be arranged to the mutual satisfaction of the Graduate School and the Textile Research Institute. C.

**Scientific and Industrial Research: Organization for India.** Sir S. S. Bhatnagar. *Indian Textile J.*, 1944, 54, 201-202. A report of an address outlining a scheme for the organization of scientific and industrial research in India. C.

# THE JOURNAL OF THE TEXTILE INSTITUTE

## ABSTRACTS

### 1—FIBRES AND THEIR PRODUCTION

#### (C)—VEGETABLE

**Cotton: Production in Northern Nigeria.** Sir Geoffrey Evans. *Textile Weekly*, 1944, 33, 906. Impressions gathered on a visit to Nigeria in February and March, 1944, are briefly reported. The village people were bringing in the final pickings from the tops of the cotton plants. The cotton was of excellent grade but weak, and the suggestion is made that a late harmattan (intensely dry north wind) had led to premature desiccation of the plants and bolls and thus to immature fibre. The crop is expected to reach 50-60 thousand bales, but not more than 10,000 will be available for export. The Hausa people make and favour coarse, rather thick hard-wearing cloth. C.

**Sperguson (Tetrachloro-*p*-benzoquinone) Cottonseed Disinfectant: Toxicity.** T. H. McGavack, L. J. Boyd, R. Terranova and D. Lehr. *J. Ind. Hyg. & Toxicol.*, 1943, 25, 98-111 (through *Bull. Hygiene*, 1944, 19, 284). Sperguson, which is used for the treatment of cotton seed, comprises 99 per cent. of tetrachloro-*p*-benzoquinone and 1 per cent. of Na<sub>2</sub>H phosphate. An intensive study has been carried out with 385 rats, and skin tests have been performed on rabbits. When a sufficient dose was given Sperguson caused loss of weight and strength, hæmoconcentration, preagonal azotæmia, leucopenia with a relative polymorphonucleocytosis, and an inconstant, late increase in the coagulability of the blood. "Carbol urine" was present when these drug effects were elicited. The drug is, however, only slightly toxic to healthy animals; it may comprise 0.5 per cent. of the diet for prolonged periods without effect. Animals in poor health may become more easily affected. Even so, there seems to be little danger of intoxication to either man or animal from this seed protectant. If all the agent were retained during handling and during its preparation for consumption by animals, concentrations would not rise above 0.2 per cent. Such a dose was found to be below the threshold of toxicity. C.

#### (D)—ARTIFICIAL

**Cellulose: Consumption by American Rayon Industry.** *Rayon Organon*, 1944, 15, 51 and 53. A table is given showing annual consumptions of wood and linters pulps, and the approximate number of bales of raw cotton linters necessary to yield the linters pulps, in the period 1930-1943. Total pulp consumption during 1943 amounted to 336,500 short tons, 84 per cent. of this being wood pulp and 16 per cent. linters pulp. C.

**Man-made Fibres: Developments.** (1) and (3) C. S. Jones. (2) H. J. Stern. (1) *India-Rubber J.*, 1944, 106, 281-285, 309-312. (2) *Ibid.*, p. 313. (3) *Ibid.*, p. 341. (1) A concise review is given of modern developments in (a) casein fibre (Aralac), (b) "Bubblfil" substitute for kapok, (c) spun glass, (d) spun rock wool, (e) nylon, (f) Velon, (g) aluminium foil coated yarn ("Reymet" foil and "Reyspun" yarns), (h) soybean fibre, (i) "Plexon" plastic-coated yarns, and (j) nettle fibre. (2) It is claimed that "Bulaira" of the French viscose manufacturers (1938-39) anticipated du Pont's "Bubblfil." (3) A reply to (2). C.

**Paper Pulp: Reactivity during Xanthation.** G. Jayme and Kuo-fu Chen. *Zellwolle, Kunstseide, Seide*, 1943, 48, 47-63 (through *Chem. Zentr.*, 1943, i, 2744 and *Chem. Abstr.*, 1944, 38, 1637<sup>4</sup>). Previous studies by various workers are reviewed. Methods for the determination of the reactivity during xanthation at accurately defined conditions and precipitation of insoluble residues are discussed. For a number of pulps residues of 8.1 per cent. (sulphites of low strength) to 43 per cent. (sulphites of high strength) were found. The reactivity

could not be expressed by a single analytical value, but can be expressed by the formula  $R_1 = [\alpha\text{-cellulose content (white content)}^2] / [\text{xanthate viscosity} \times 10,000]$ . The reactivity of these pulps is closely related to the nature of the primary lamella as it is influenced by the hydrolytic or oxidative decomposition of the lamellae. The reaction inertia of the stronger sulphate products is related to the hydrolysis of the primary wall. Good filtering property is governed not only by the  $R_1$  value, but also by the amount of ash, resin, etc. The influence of the various treatments during viscose-manufacture and of the acid and alkali cellulose after-treatment are discussed. The reactive rayon fabrics must have low strength values in all cases. C.

**Xanthated Soda-pulp Fibres: Swelling and Solution.** W. Schramek and H. Schwarz. *Leipzig. Monats. Textil-Ind.*, 1941, 56, 11-16 (through *Chem. Zentr.*, 1941, ii, 133 and *Chem. Abstr.*, 1944, 38, 1637'). For the solution of xanthated soda pulp fibres the outer layer surrounding the fibre must be dissolved first and then various stages of decomposition take place with simultaneous extensive swelling. The process of solution and the appearance of the fibre undergoing this process are described in detail. C.

**Cellulose Pulps: Sources and Preparation.** W. Schieber. *Jentgen's Kunstseide u. Zellwolle*, 1941, 23, 228-234 (through *Chem. Zentr.*, 1941, ii, 2159-2160 and *Chem. Abstr.*, 1944, 38, 1876'). Possible raw materials for the German pulp and rayon industries apart from forest trees, are straw, potato tops, flax and hemp chaff, broom, nettle, sunflower, cornstalks and Italian reed (*Arundo donax*). Details are given of the structure, available quantities and cellulose contents of these plants and of the composition of the pulp obtained by the different methods. Sulphate pulp may show 90 per cent.  $\alpha$ -cellulose and still contain 25-30 per cent. pentosan. A method is described for the pulping of pine, beech, potato tops, etc., by a modified sulphate process in which an acidic pre-hydrolysis renders the hemi-celluloses soluble in alkali. The solution from the acid hydrolysis contains about 20 per cent. of the wood in the form of fermentable sugar. The harmful effluents from the sulphite process may be improved by diffusion washing and rational evaporation. C.

**Casein Fibres: Production.** P. Eckert and E. Swatck. *Kleipzig's Textil-Z.*, 1941, 44, 983-986 (through *Chem. Zentr.*, 1941, ii, 2894 and *Chem. Abstr.*, 1944, 38, 1883'). The precipitation of casein from skim milk by acid is improved by higher temperatures of precipitation or of after-warming. At 20° the casein precipitates only poorly and the whey nearly always remains turbid; however, during after-warming there takes place a gradual balling and flocculation of casein particles. At higher precipitation temperatures the separation takes place immediately in large flakes. Temperatures above 72° lead to a simultaneous precipitation of the albumin (whey protein). If an insufficient amount of acid is used for the precipitation and if the pH value of the whey after the precipitation is about 4.5-5.0, then the casein precipitates in large flakes; however, if the amount of acid is increased the casein precipitates in small flakes. The most favourable acid concentration is that corresponding to the isoelectric point. The viscosities of alkaline casein solutions of the same composition depend on the pH value and the precipitation temperature. The lower the pH value the more slowly the viscosity of the solution increases. At the same pH value but different precipitation temperatures the higher precipitation temperature causes a quicker increase of viscosity. The method of adding the acid has no influence on the viscosity. The properties of alkaline casein solutions whose casein was precipitated at a higher pH value can be influenced by supplementary acid precipitation. An increase of the ripening temperature causes a rapid increase of the viscosity. C.

**Protein Fibres: Production.** H. P. Lundgren and R. A. O'Connell. *Ind. Eng. Chem.*, 1944, 36, 370-374. Investigations of the viscosity and electrophoretic behaviour of solutions of mixtures of native and denatured egg albumin and feather keratin with sodium alkyl benzenesulphonate are discussed and evidence is given of an unfolding of the native egg albumin structure and of the formation of protein-detergent complexes. When precipitated by salts the protein-detergent complexes are either flocculent or slimy, depending on the ratio of protein to detergent. Dispersions of egg albumin and chicken-feather keratin with alkyl benzenesulphonate form ductile precipitates when the ratio

lies between 40-60 and 60-40 protein-detergent. Viscous solutions of mixtures having these proportions and compositions above 17 per cent. of total solids can be extruded through a spinneret into a bath of salt solution to give fibres that can be stretched and reeled. When allowed to dry the fibres are weak and attempts to produce orientation by drawing in the presence of steam have been unsuccessful. After removal of the detergent, e.g. with aqueous acetone, it is possible to draw the fibres over 300 per cent. in live steam. After proper annealing at lower temperatures, such fibres exhibit positive birefringence and a high degree of molecular orientation as determined by X-ray diffraction. The stretching is accompanied by an increase in tensile strength and in water resistance, and a decrease in the range of elastic deformation. Fibres have been prepared from chicken-feather keratin and egg albumin with tensile strengths of over 70,000 lb. per sq. in., which compare favourably with those of natural fibres. The fibres with a high degree of molecular orientation show moisture retention comparable to that of wool. C.

#### PATENTS

**Polyamide Filaments: Treatment to Improve Impact Strength and Thermo-extensibility.** E. I. Du Pont de Nemours & Co. B.P.561,344 of 12/10/1942: 16/5/1944 (Conv. 13/10/1941). Synthetic linear polyamide filaments of improved impact strength and thermo-extensibility are obtained by treating orientated filaments of synthetic linear polyamides in a solution of a phenol in a solvent that is a non-solvent for the filaments, for a time and at a temperature and concentration insufficient to dissolve the filaments, removing the phenol by means of a solvent that does not dissolve the filaments, and finally drying, the various treatments being carried out while the filaments are under tension. The concentration of the phenol solution and the time of soaking are so regulated that the filament (water saturated) absorbs at least 4 per cent. of its weight of the solution, but does not absorb enough to become sticky or to dissolve. Filaments processed in this manner, especially those ranging from 30 to 70 mils in diameter, are useful as strings for tennis and similar rackets. Large filaments can also be used as tyre cords. C.

**Rayon Spinning Bucket Cover.** American Viscose Corporation. B.P.561,687 of 5/2/1943: 31/5/1944 (Conv. 20/3/1942). A spinning bucket cover has a number of radially slidable cover-locking members arranged to be thrown centrifugally into engagement with a spinning bucket on rotation therewith, the members having bucket-engaging portions at their outer ends and upwardly and inwardly sloped portions arranged at their inner ends and adapted to be embraced and to be moved inwardly by a common encircling device whereby release of the cover-locking means from the bucket is effected. The cover may be provided with upstanding means affording manual gripping thereof, and with manual releasing means. A removable cake-supporting member and a device insertable into the bucket through the cover for gripping the cake-supporting member and releasing the cover-locking means may be provided. C.

**Polyamide Compositions: Production.** E. I. Du Pont de Nemours & Co. B.P.561,701/2 of 7/8/1942: 1/6/1944 (Conv. 10/9/1941). (1) A composition suitable for use in the manufacture of filaments, films, sheets, coatings and the like comprises a synthetic linear polyamide plasticized with a mixture consisting of a phenol and a neutral, completely esterified ester of a carboxylic acid in which at least one of the alcohol residues is the residue of an aliphatic carboalkoxy alcohol wherein the organic radical connecting the alcoholic hydroxyl and the carboalkoxyl group contains not more than six carbon atoms. The phenol may be an alkyl ester of a fatty acid containing a hydroxyphenyl nucleus attached to the acid residue. (2) A composition suitable for use in the manufacture of filaments, films, sheets, coatings and the like comprises a synthetic linear polyamide plasticized with a mixture consisting of a solvent plasticizer and a neutral completely esterified ester of a carboxylic acid in which at least one of the alcohol residues is the residue of an aliphatic carboalkoxy alcohol wherein the organic radical connecting the alcoholic hydroxyl and the carboalkoxyl group contains not more than six carbon atoms. The solvent plasticizer may be a sulphonamide. The resulting plasticized polyamide compositions and articles made from them are very pliable and do not become tacky at moderately elevated temperatures. C.

**Monofilaments: Production.** American Viscose Corporation. B.P.561,772 of 15/10/1942:5/6/1944 (Conv. 18/11/1941). A method of forming a unitary filament comprises the steps of fusing a bundle of thermoplastic filaments, e.g. a vinyl resin, subjecting the filamentary material to a superficial swelling treatment, drying, and polishing with pumice or other abrasive powder wetted with olive oil or other lubricant. Preferably, the filamentary bundle is treated with a solvent or swelling agent, and after evaporation of the agent is subjected to the process described in B.P.560,535, or any other suitable procedure for converting it into a monofilament, which is then polished. The monofils may be used in the production of hosiery, knitted or woven fabrics, e.g. nets, violin strings, strings for tennis rackets, bristles, artificial horsehair, etc. C.

**Viscose Spinneret Alloy.** Baker & Co. Inc. (Newark, N.J.). U.S.P.2,334,890. An alloy for a viscose spinneret consists of Pt 90-95 per cent., Rh 3-7.5 per cent. and Ru 2-5 per cent. C.

**Molten Glass Spinning Apparatus.** Owens-Corning Fiberglas Corporation. U.S.P.2,335,135. The bottom of the receptacle that holds the supply of molten glass is furnished with a number of rows of nipples through which the glass descends in a number of fine streams. C.

**Casein Fibres: Treatment.** Karl Börner (Germany; vested in the U.S. Alien Property Custodian). U.S.P.2,335,576. Fibres spun from casein and hardened by formaldehyde are floated in a bath containing not more than 0.1 per cent. of ammonia. C.

**Viscose-Sulphonamide Stretch-spun Rayon: Production.** E. I. Du Pont de Nemours & Co. U.S.P.2,335,592. A stretch-spun filament of "improved loop tenacity" is obtained from a mixture of viscose and a sulphonamide of more than 10 C atoms, at least four of which are in a straight chain, the N atom not bearing a substituent. C.

**Water-repellent Rayon Filaments: Spinning.** E. I. Du Pont de Nemours & Co. U.S.P.2,335,980. Water-repellent filaments and films are obtained by extruding into a regenerating bath an aqueous solution of cellulose in a quaternary ammonium compound,  $Z \cdot CH_2 \cdot N(t) \cdot Hal.$ , and then heating the product to split of the volatile tertiary amine represented by  $N(t)$ ; Z is an aliphatic radical of at least 10 C atoms attached to the  $CH_2$  group through a trivalent N atom. C.

**Rayon Yarn Shrinkage Controlling and Winding Device.** Industrial Rayon Corporation. U.S.P.2,336,019. In a method for controlling the shrinkage of rayon, the thread is given a temporary undulating form, advanced in this form in helical turns along the periphery of a thread-advancing thread-storing device, and then treated with a shrinking medium to eliminate the undulations. C.

**Depilating Hides.** G. Berg (to J. Hüchel's Söhne). D.R.P. 731,682 of 14/1/1943 (through *Chem. Abs.*, 1944, 38, 657). An apparatus for the mechanical depilation of hides is described; it produces an un haired hide and hair suitable for the hat industry. W.

## 2—CONVERSION OF FIBRES INTO FINISHED YARNS

### (A)—PREPARATORY PROCESSES

**Cotton Mill: Modernization.** J. Buckley. *Textile Manufacturer*, 1944, 70, 207-209, 253-255. An illustrated account is given of the machinery and lay-out that might be adopted to modernize a 64,440 mule spindle mill producing about 40,000 lb. of (average) 36s double-roving yarn in 48 hours. The plan is based on the "combined operations" of single-process lapping, lap drawing, and high-draft ring spinning. C.

### (B)—SPINNING AND DOUBLING

**Vibrationless Speed Frame Drive.** Messrs. Tweedales and Smalley Ltd. *Textile Weekly*, 1944, 33, 870-875. An illustrated account is given of a new model speed frame in which previous noisy gearing, especially that from the differential pulley to the bobbin shafts, is replaced by helical-cut gears and chain drives. The drafting is by a 4-line roller system. C.

## (C)—SUBSEQUENT PROCESSES

**Nylon Yarn: Twist Setting.** *Textile Manufacturer*, 1944, 70, 217-218. The writer discusses the problem of setting the twist in a rayon yarn without at the same time setting the yarn as a whole in its wound form, e.g. loops. A test for "twist liveliness" (snarling tendency) is described and also a creasing angle test for the extent of yarn setting. Patented processes for twist setting are reviewed. [See E. I. Du Pont de Nemours Co., B.P.519,038 and 553,303 (*Summary*, 1940, p. 207 and 1943, p. 370); Imperial Chemical Industries Ltd., B.P.559,369 C.

## PATENTS

**Spindle Driving Apparatus.** F. Heald and Tweedales & Smalley (1920) Ltd. B.P.561,352 of 14/11/1942:16/5/1944. In a positive drive for spindles of spinning and twisting machines of the kind in which each spindle is driven by a pair of spiral or bevel gears, one gear of each pair is rotatable on the bolster of the spindle and drives the latter and the other is mounted on a driving shaft section, a number of which are detachably coupled together to constitute a main driving shaft, one section being provided for each spindle. The drive is transmitted to each spindle from that spiral gear which is rotatable on the spindle bolster through the intervention of a clutch which may be on the shaft section or on the spindle unit. The drive is transmitted to the bobbin platform in such a manner that the spindle retains its flexibility for carrying varying unbalanced loads, the bobbins being driven from the platform by pins or other driving members. Each spindle driving unit is provided with a control member for putting the clutch out of operation and subsequently applying a brake for bringing the spindle to rest, movement of the control member in the opposite direction releasing the brake before engaging or allowing the engagement of the clutch to start the spindle. A portion of each spindle bolster, together with the spiral gears and other attendant parts, is enclosed in a gear case which forms an oil well in which one of the gears is partly submerged. The spindle itself can be lifted out of its bearing without disturbing the gear case. The oil for lubricating the spindle and the oil for the gears are entirely separated. The gear case, spindle, gears and shaft section constitute one self-contained unit which can be bolted on to the spindle rail of the machine, each spindle and driving unit being independent of its neighbour. C.

**Portable Spindle Brake.** Celanese Corporation of America. U.S.P.2,334,748. A portable brake for a spindle assembly that has an oil well in its swing stem comprises a handle, a lever arm extending at an angle from the handle and ending in a brake shoe, and a pin at the junction of the handle and lever arm for insertion in the oil well. C.

**Glass Fibre Bat.** Owens-Corning Fiberglas Corporation. U.S.P.2,335,102. A light-weight, strong, resilient bat of glass fibre is obtained by simultaneously depositing from a gaseous atmosphere glass fibre and an aqueous emulsion containing petroleum and a water-soluble, thermo-setting aldehyde condensation product, drying off the water so that the oil and resin separate on the surface of the fibre, fluffing up the fibre into a loose mat, and applying heat to set the resin and stiffen the mat. C.

**Ring Twisting Frame Traveller.** Victor Ring Traveler Co. U.S.P.2,335,121. The claim is for a traveller that rides vertically on a twister ring with its main plane radial to the direction of travel. The head portion has a rounded inner bearing surface and the foot portion is flattened where it engages the ring. C.

**Ring Traveller.** Herr Manufacturing Co., Inc. U.S.P.2,335,566. The claim is for a traveller that is much wider than thick and has rounded edges so that it provides a smooth, full-sweep, thread-engaging surface, and offers a minimum wind resistance. C.

## 3—CONVERSION OF YARNS INTO FABRICS

## (C)—WEAVING

**Weaving Efficiency: Loom Stoppages.** "Portex." *Wool Rec.*, 1944, 65, 799, 801. In weaving fancy woollens and worsteds on the standard dobby loom, shuttle-changing is the chief source of stoppages. Its relation to the count of yarn, size of weft pirn, and sett and width of cloth is discussed. W.

## PATENTS

**Winding Machine Stopping Mechanism.** Universal Winding Co. B.P. 561,219 of 8/10/1942:10/5/1944 (Conv. 28/11/1941). A yarn winding machine having stopping mechanism is provided with a device for arresting the operation when the package reaches a predetermined size, comprising a member actuated continuously by the drive of the machine and constituted by a going member that is movable bodily by and with the growth of the package. This arrangement ensures that undue pressure on the package is obviated when the stopping mechanism is brought into operation. C.

**Loom Cloth Roller Grip.** J. A. Sutcliffe. B.P. 561,247 of 6/11/1942:11/5/1944. The cloth on the cloth roller is gripped against the sand roller by a flexible connection that is anchored at one end and passed under the cloth roller up and over the sand roller down to and under a rail or other convenient fitting, up and over the cloth roller and down to an anchorage, the amount of grip between the cloth roller and the sand roller being regulated to any particular requirement by a screw connection or other tension producing device interposed in the flexible connection. A spring or springs may also be provided in the flexible connection for taking up any variation in tension therein. C.

**Patterned Fabrics: Knitting.** R. Kretser (Bayside, Long Island, U.S.A.). B.P. 561,339 of 7/9/1942:16/5/1944. A method of knitting a multi-yarn fabric comprises the steps of knitting each one of a number of yarns, each yarn being fed exclusively to one of the needles of a multi-feed knitting machine in selected intermittent courses to form an intermittent series of individual stitches wale-wise of the fabric, from each of the yarns, knitting a number of other yarns to form a series of course-wise stitches, floating these yarns across the wrap stitches and floating the wrap stitch yarns across the course-wise stitches in the courses where the wrap stitches are not formed. Yarns of different colour and type may be used. Patterns similar to those produced on a loom are produced by this method. Details are given of a suitable circular knitting machine for carrying out this method of knitting. C.

**Knitted Glove.** C. F. Schuessler (Chicago). B.P. 561,449 of 2/2/1943:19/5/1944 (Conv. 17/1/1942). A knitted glove has its front side provided with an area of close stitches and the portion of its back aligned with the area of close stitches formed of relatively loose stitches. The finger and thumb portions are provided on their front sides with areas of close stitches and their backs are formed of relatively loose stitches. The finger and thumb portions have at least one row of relatively loose stitches encircling their bases whereby they are joined to the body of the glove. If desired tight stitches may be provided on the inner face of the glove body and the bottom portion of the glove. The tightly knitted areas resist wear and the loose stitches on the back provide for freedom of movement and flexibility. The glove tends to form a curve which fits the normal curvature of the hand. C.

**Loom Shuttle Guard.** F. Stuttard and J. O. Whittaker. B.P. 561,751 of 27/11/1942:2/6/1944. A loom shuttle guard comprises front and rear rods spaced at any required distance apart and interconnected. The rear rod is pivoted and slidable in two end brackets fixed to the sley cap, each bracket being formed with a ledge on which a cranked portion of the front rod normally rests, a block adjustably mounted on the rear rod being formed with surfaces adapted to interlock with corresponding surfaces on an intermediate bracket and retain the guard in its operative position on the ledges. The guard is capable of being moved in an endwise direction in the brackets against the action of a spring for the purpose of effecting the disengagement of the interlocking surfaces and when this disengagement has been effected the guard can be turned in an upward direction until it rests against the front of the sley cap in which position it is out of the way of the weaver. When the loom is set in motion the momentum of the sley automatically causes the guard to fall down to its operative position. C.

**Pile Fabrics: Production.** A. E. O'Dell (Collins & Aikman Corporation, U.S.A.). B.P. 561,769 of 8/8/1942:5/6/1944. A method of face to face weaving of **W** pile fabrics includes the steps of interconnecting the grounds with pile-forming yarn, temporarily forming a number of sequential loops, free

from interlacing with the grounds, in the interconnecting pile warp yarn and supporting such loops at their bights by supported elements lying in different planes which are spaced from one another in a direction normal to the grounds, any one such element having loops on only one side of it, releasing the support of the bights, spreading the grounds, and cutting the interconnecting pile-forming yarn to separate the fabrics. The method may include the additional step of forming a pile loop secured at both ends in a single ground. The two pile fabrics are woven simultaneously on a loom equipped with stationary warp-wise gauges having free ends. C.

**Cellulose Ester Insect Screen.** C. Dreyfus. U.S.P.2,334,754. The claim is for an open-mesh fabric with yarns made by twisting and adhesively setting strips of cellulose ester foil. C.

**Circular Loom Weft Feeler Motion.** B. F. Goodrich Co. U.S.P.2,335,111. The claim is for a weft feeler arm which is pivoted to the shuttle of a circular loom and actuates a circuit breaker to stop the loom when the weft on the bobbin reaches a pre-determined condition. C.

**Weft Tensioning Device.** Draper Corporation. U.S.P.2,335,142. Normally stationary means are mounted on the breast beam of the loom for independently gripping the weft and cooperate with means carried by the sley to take up slack in the weft as the sley beats forward. C.

**Self-threading Shuttle.** Draper Corporation. U.S.P.2,335,534. The claim is for means to prevent the weft from rising up out of the side delivery eye in the shuttle. It employs a bundle of resilient fibres so arranged that they can bend to admit the weft, but prevent it from rising up. C.

**Shuttle Weft Tension Equalizing Device.** Draper Corporation. U.S.P.2,335,483, 2,335,563. The threading block of a shuttle for an automatic weft-replenishing loom contains friction means for engaging the weft, which cooperate with independent means actuated by the weft to vary the friction in inverse relation to the tension in the weft. C.

**Self-threading Shuttle.** Draper Corporation. U.S.P.2,335,564. A thread guiding device, controlled by resilient means, is pivoted in the passage leading from the threading block so that it can guide the weft into position and hold it against displacement by looping. C.

**Tubular Fabric Loom.** National Rubber Machinery Co. U.S.P.2,335,654. A horizontal circular loom for weaving tubular fabric on inflexible mandrels has change-speed gearing connections between (a) the drive for the revolving shuttle and shed-forming mechanism and (b) the mandrel-conveyor so that the speed of the conveyor is variable with respect to the speed of the loom proper. C.

**Creel-to-Beam Tape Frame.** S. P. Ouzts (Hodges, S.C.). U.S.P.2,335,880. The claim is for a tape frame on which yarn is fed directly to the sow-box from a creel *via* a walk-way. C.

**Elastic Filament Winding Apparatus.** Filatex Corporation. U.S.P.2,335,965. In a machine for winding elastic filaments under tension, means are provided for increasing the rate of rotation of the supply package, and the greater rate of operation of the winding-on means, in proportion to the increase in diameter of the wound package. C.

**Yarn Winding Machine.** Celanese Corporation of America. U.S.P.2,335,975. The claim is for means to cause the traverse frame assembly that carries the reciprocating yarn guide to recede steadily at a controlled rate from the axis of the yarn package as the package builds up. C.

**Knitting Machine Stop Mechanism.** Michael Wachsman. U.S.P.2,335,979. A thread-supporting arm is connected to a lever pivoted inside a box and an operating arm in the box, on the same lever pivot, is kept in sliding engagement with a spring that trips the lever on failure of the thread. C.

#### 4—CHEMICAL AND FINISHING PROCESSES

##### (G)—BLEACHING

**Persulphates: Use in Bleaching and Desizing.** J. Rièrè. *Teintex*, 1941, 6, 130-133 (through *Chem. Zentr.*, 1941, ii, 1345 and *Chem. Abstr.*, 1944, 38, 1885<sup>6</sup>). The author discusses the production and properties of persulphates.

They are mostly stable in solution at 35°, but at 80° a brisk evolution of oxygen occurs. Metals have a strong catalytic action on this reaction. Since acid salts and free sulphuric acid are formed in the decomposition of the persulphates, care must be taken to provide for the neutralisation of these acids if the fabric is not to be converted into weaker hydrocelluloses. In the work reported persulphates were used for the desizing of cotton fabrics. For continuous operation the bath contained 2 g. of potassium persulphate, 15 c.c. of caustic soda of 40° Bé., 1 g. of fatty alcohol sulphonate and 2 g. of soap per l. The bath temperature was 80–90°. Hydrogen or sodium peroxide can be added to the bath to improve the bleaching action. The process can also be combined with kier boiling if 1 kg. of K persulphate is added to 1500 l. of the caustic soda at 50–60° and the liquor is then slowly heated to 100°. The active oxygen in the persulphate can be determined by splitting off of nitrogen from hydrazine according to the method of Pannain, by the use of oxalic acid and silver peroxide according to Kempf or by the methyl alcohol method of Marie and Kunel. C.

#### (H)—MERCERISING

**Cotton-Rayon Cloths: Mercerising and Bleaching.** P. Colomb. *Teintex*, 1941, 6, 163–167 (through *Chem. Zentr.*, 1941, ii, 2158 and *Chem. Abstr.*, 1944, 38, 1646<sup>6</sup>). General information is given concerning the history and varieties of artificial fibres. Staple fibres of the viscose and cellulose acetate type are discussed. Mixed weaves of cotton and viscose rayon are mercerised with a mixture of caustic soda and caustic potash or with addition of sodium chloride. In this process the gloss is reduced, but the dyeing qualities are increased. Cuprammonium staple fibre is mercerised at 15–20° with caustic soda (7–5° Bé.) and a wetting agent. Mercerising of cloths containing 35, 55 and 75 per cent. artificial fibres mixed with cotton is discussed. The material is desized with Rapidase or Diastafor, scoured with soda or sodium phosphate and bleached in sodium hypochlorite or with hydrogen peroxide in water glass. C.

**Cotton-Wool Mixture Fabrics: Mercerisation.** J. Besançon. *Teintex*, 1941, 6, 102–104; *Monit. Maille*, 1941, 51, 33–35 (through *Chem. Zentr.*, 1941, ii, 1571 and *Chem. Abstr.*, 1944, 38, 1885<sup>4</sup>). Data are given on the effect of alkali on wool, the dyeing of semi-wool fabrics with sulphur dyes, the mercerisation of cotton fabrics containing wool and subsequent dyeing with aniline black, and the mercerisation of cotton fabrics with wool in the selvages. Caustic soda liquor of 28° Bé. does not cause any appreciable damage to wool; the damage is caused only on washing when the alkali is diluted to 19° Bé. Under 19° Bé., no damage takes place. The impregnation of fabrics with formaldehyde protects the wool very well; however, it is more economical to pass through the dangerous alkali region by rapid washing with cold water. During the acidification it is advantageous to leave in the rinsing bath the sodium sulphate that is formed by the reaction between sulphuric acid and caustic soda, as it has a protective action on the fibre. The acid must be washed out carefully from the wool because of its effect on the dye. Wool that has not been completely deacidified absorbs aniline black. Alkali-damaged wool absorbs direct dyes at a lower temperature than does wool that has been treated in the ordinary way. The alkali acts chemically on the sulphur group of wool. C.

#### (I)—DYEING

**Dye Solution Concentration Recording Device.** T. B. Davenport. *J. Sci. Instruments*, 1944, 21, 84–86. By means of a photo-electric device for measuring the light absorption of a dye solution which is being circulated through a mass of textile material, the variation in concentration of dye with time can be derived and the progress of the dyeing operation followed in detail. Light from a 12V, 36W spot-light bulb is modulated by a rotating sector disk and focused by a lens on the flattened portion of a cross-tube connecting towards their upper extremities the two limbs of a U-tube containing the temperature controlled coloured solution which circulates rapidly through the system under the action of a rotating stirrer. The textile material is contained in a 3 in. length of glass tubing fitted at the lower end with a perforated porcelain disk allowing free circulation of the dye solution, the whole fitting snugly in one limb of the U-tube. The light is partially absorbed by the coloured solution circulating through the cross-tube and is then passed through a suitable colour

filter and focused on the cathode of a vacuum photo-cell by a second lens. The photo-cell is placed in the anode circuit of a pentode valve so connected that the voltage developed between anode and cathode shall be a logarithmic function of the photo-current. This voltage is applied to the input of a three-stage resistance capacity coupled amplifier, the output of which is rectified by a double-diode, and measured on a galvanometer of low sensitivity inserted in the cathode lead. The relation between solution concentration and galvanometer reading is linear. The construction and operation of the apparatus are described in detail, and diagrams and some typical results are given. C.

**Rayon Staple Fibre: Fast Dyeing.** F. G. Krüger. *Deut. Textilwirt.*, 1941, 8, No. 11, 31-33 (through *Chem. Zentr.*, 1941, ii, 1449-1450 and *Chem. Abstr.*, 1944, 38, 1643<sup>9</sup>). Rayon staple fibres are classified as (1) those that can be dyed with weakly acid or nearly neutral acid dyes (casein fibres, animalized staple fibre, Pe-Ce, nylon, etc.), (2) those that can be dyed with all dyes applicable to vegetable fibres (viscose, cuprammonium rayon, etc.), and (3) those that need special dyes, e.g. acetate rayon. Directions are given for dyeing with indanthrene and sulphur dyes. Special equipment needed for fast dyeing of loose staple fibre is described. C.

**Viscose Yarn Cakes: Dyeing.** C. M. Whittaker. *J. Soc. Dyers & Col.*, 1944, 60, 109-114. The advantages of dyeing viscose yarn in cake form are pointed out and a cake dyeing machine is described. Various precautions necessary in the dyeing process are outlined. Details are given of procedures for the application of direct, vat and azoic dyes, and difficulties experienced in attempts to use sulphur dyes and to apply vat dyes by the pigment padding process are briefly discussed. C.

**Dyed Cotton Fabrics: Deterioration by Light.** Sulphur Dyed Textile Materials: Accelerated Ageing Test. See Section 5C.

**Artificial Leather Base Fabrics: Dyeing and Dressing.** P. Hardy. *Teintex*, 1941, 6, 96-99 (through *Chem. Zentr.*, 1941, ii, 1329-1330 and *Chem. Abstr.*, 1944, 38, 1882<sup>8</sup>). Cotton and rayon are used for base fabrics for artificial leather. Formulae are given for dyeing with aniline black, sulphur black and logwood. Formulae are also given for mottled colours. Dressing of cotton fabrics with size, or better, with emulsified vinyl resins such as Emulsion 5000 (Soc. Rhone-Poulenc) is described. Rayon fabrics are desized with sodium phosphate and a fatty alcohol sulphonate and then dyed with direct dyes. Dressing can then be done with Emulsion 5000 or with a polyacrylic acid resin, as e.g. Plextol D (Röhm and Haas). Coating is carried out in an apparatus in which the fabric passes between rollers through a trough and is freed from excess impregnating material by means of a scraper. C.

**Chrome Green: Inflammability.** H. Berger. *Arbeitsschutz*, 1941, 141-144 (through *Chem. Zentr.*, 1941, ii, 2475 and *Chem. Abstr.*, 1944, 38, 1882<sup>6</sup>). Dry mixtures of Chrome Green should not be prepared in heavy edge mills. It is advisable to add 2 per cent. liquid petrolatum to the mixture. Finished mixtures of Chrome Green should be removed immediately from the proximity of pulverizing machines; they should be kept in fireproof containers. Dampness and impurities of vegetable oils should be avoided. Berlin blue is indicated to be the dangerous component of Chrome Green. C.

**Colour Lakes: Formation on Fuller's Earth.** H. Goldhahn. *Angew. Chem.*, 1941, 54, 377 (through *Chem. Zentr.*, 1941, ii, 2871 and *Chem. Abstr.*, 1944, 38, 1882<sup>9</sup>). Adsorption colours of different hydroxyazobenzene dyes on Tonsil (clay), floridin and aluminium hydroxide are discussed. The hydroxybenzenes corresponding to the dyes frequently give, on adsorption on fuller's earths from non-aqueous solution, characteristic colours which often correspond to the colours produced by the dyes. It is questionable whether colour lakes occur on the adsorption of hydroxybenzenes. C.

**Substantive Azo Dyes: Production.** C. F. H. Allen and F. P. Pingert. *J. Org. Chem.*, 1944, 9, 50-54 (through *Chem. Abstr.*, 1944, 38, 1882<sup>2</sup>). A discussion of the basic structure of substantive dyes and the term "substantivity," leads to the conclusion that a crossed-conjugated system of multiple linkages and particle size are two factors which contribute to substantivity. Multiple conjugation is a special case of certain resonating systems and it is not unlikely

that the electronic resonance formed causes the easily reversible agglomeration of the dye molecule to particles of roughly molecular dimension. The *o*-terphenyls can be considered as stilbenes in which a benzene ring takes the place of the ethylene group and 4:4'-diamino-*o*-terphenyl may give azo dyes which should be substantive for cotton. When this compound is tetrazotised and the tetrazo solution is added to an alkaline solution of a coupling component, monoazo dyes are easily formed. The coupling with two molecules of the naphthol is very slow unless the solution is strongly alkaline. Monoazo dyes formed with such coupling components as G-acid, J-acid, and urea do not colour cotton, but dye wool from an acid bath. A disazo dye is prepared by coupling tetrazotised 4:4'-diamino-*o*-terphenyl with 2 molecules of H-acid. When tetrazotised and coupled with H-acid in strongly alkaline solution, 4:4'-dinitro-*m*-terphenyl gives a dye which dyes cotton reddish blue at pH 7-8 in the presence of magnesium sulphate and shows greater substantivity than the isomeric terphenyl derivatives. 4':4''-Dinitro-*p*-terphenyl is slowly catalytically reduced at 110° and high pressure. Tetrazotised and coupled with H-acid, a violet dye is formed which dyes cotton directly in the presence of magnesium sulphate. C.

#### (K)—FINISHING

**Cellulose Ester Plasticizers: Solubility in Liquid Ammonia.** P. C. Scherer and E. O. Sternberg. *Rayon Textile Monthly*, 1944, 25, 143-145. Liquid ammonia was patented as a solvent for nitrocellulose and cellulose esters in 1921 (Nitrogen Corporation; B.P.182,488; U.S.P.1,544,809 and 1,544,812), but it was soon found that a plasticizer would have to be added in order to obtain flexible films from such solutions. The present authors have measured the solubility in liquid ammonia, at its boiling point, of a large number of plasticizers. The technique is described and the data are tabulated with a note where necessary to say whether or not the agent is stable in liquid ammonia. The triaryl phosphates are only slightly soluble, but the simple alkyl phthalates (C<sub>1</sub> to C<sub>6</sub>) are completely miscible with liquid ammonia. The solubility decreases rapidly with increase in the length of the alkyl chain. Diphenyl phthalate reacts vigorously. The glycol esters are freely soluble and stable in liquid ammonia but glycolate plasticizers react. Two agents of the sulphonamide type were found to be completely miscible and quite stable. C.

**Silk and Rayon Tricot Goods: Delustring.** J. Dutreillis. *Mon. Maille*, 1941, 51, No. 716, 35-36 (through *Chem. Zentr.*, 1941, ii, 1088 and *Chem. Abstr.*, 1944, 38, 1645<sup>3</sup>). In delustring with barium chloride and sodium sulphate solution it is best to centrifuge and not to rinse after the first bath. If barium hydroxide is used, a stable compound between the fibroin and barium hydroxide is formed; this is wash-proof and the goods can be rinsed to effect a more uniform delustring. A concentrated sodium sulphate solution must be used to convert the hydroxide completely into barium sulphate. It is better to delustre after dyeing than in the dye bath. Different delustring agents must be employed very finely divided; Gardinol is a suitable dispersing agent. Good adhesion of the delustring agent can be brought about with a penetrating agent or gelatinised starch followed by treatment with an oily softening agent. C.

**Sulphonated Peanut Oil: Preparation and Properties.** J. B. Gallent. *Amer. Dyes. Rept.*, 1944, 33, 148-149, 156. Uses of sulphonated oils are mentioned and the advantages and disadvantages of peanut oil as a raw material are pointed out. The properties of products obtained by sulphonating peanut oil with 98 per cent. sulphuric acid, fuming sulphuric acid, fuming sulphuric acid (40 per cent.) + sulphuric acid (60 per cent.), and chlorosulphonic acid, and by sulphonating a mixture of 75 per cent. peanut oil and 25 per cent. castor oil are described. A brief report is given of a test in which samples of cotton cloth were treated with a mixture of water 1,000 g., corn starch (40 fluidity) 60 g., oil (50 per cent. fatty matter) 50 g., kept in screw-cap jars for 7 days at 50° C., and then examined for odour and stain at the end of this period. Sulphonated peanut oils and a commercial product containing 70 per cent. peanut oil, 30 per cent. castor oil and 0.25 per cent. lecithin were used. The treated samples were free from odour and stain except samples containing oil prepared by sulphonating a year-old sample of peanut oil. These developed a slight odour, but a similar oil containing 0.25 per cent. lecithin gave satisfactory results. In

a mill test in which a peanut+castor oil product was used in a finishing mixture the cloth (blue denim) was processed and then stored for four weeks without the development of odours, and had a good handle, "slick" finish and bright colour. C.

**Cellulose Fibres: Hydrophobing.** H. J. Henk. *Kunstseide u. Zellwolle*, 1941, 23, 217-18 (through *Chem. Zentr.*, 1941, ii, 1572 and *Chem. Abstr.*, 1944, 38, 1883<sup>3</sup>). Free hydrophilic OH groups of cellulose, which cause the strong swelling of artificial fibres, can be rendered inactive by conversion to ethers or esters by means of a number of chemicals and the fibres can be crease-proofed by means of urea-formaldehyde products. These treatments are discussed in detail. C.

**Mechanical Finishes on Cotton and Rayon Fabrics: Increasing Permanence.** *Textile Mercury & Argus*, 1944, 110, 400 etc., 424 etc., 484 etc., 561 etc. A broad review of old and new methods. The influence of moisture content in Schreiner and lustre finishes is mentioned, and references are made to patented processes, in which synthetic resins, formaldehyde, organic quaternary ammonium compounds, and other special agents are used. C.

#### (L)—PROOFING

**Textile Materials: Water-, Fire- and Rot-proofing.** G. Stühmer. *Text. Ring*, 1943, 1, 22-24 (through *Chem. Zentr.*, 1943, ii, 1065 and *Chem. Abstr.*, 1944, 38, 1646<sup>6</sup>). Water-repelling, air-admitting impregnation is effected with aluminium acetate or formate (preferably aluminium triformate) and soap or paraffin emulsions. Textiles can be waterproofed with rubber, waxes, synthetic resins, etc. Synthetic single-bath impregnating agents are Ramasit, Imprägnol, Paralin and Anthydriol PL. Other waterproofing agents are Velan, Persistol, Netumid, Hydrophobol and Rotal. Suitable antiseptics are copper salts, formaldehyde, Preventol, Raschit and Amycol. Netumid protects against gnats, ammonium salts, phosphates, tungstates and stannates protect against fire, and Eulan protects against moths. C.

**Coated Fabrics: Water Vapour Permeability.** See Section 5C.

**Army Ducks: Finishing and Mildew Proofing.** E. C. Bertolet. *Amer. Dyes Rept.*, 1943, 32, 214-219, 226-227. Mineral dyeing and vat dyeing procedures and methods for the production of water repellent and mildew-resistant finishes on army ducks to comply with the U.S. Quartermaster Depot specifications are described. Mildewproofing compounds and methods of applying them are critically discussed, and the results of tests and of practical experience with copper, cadmium and silver compounds, phenyl mercury compounds, o-phenylphenol, and pentachlorophenol are reported. The mercurial antiseptics mentioned include phenylmercuric acetate and oleate, phenylmercuro-2:2':2''-nitritotriethanol lactate, and 9-phenylmercuro-10-acetoxy-12-octadecenoic acid. C.

**Vulcanised Rubber: Deterioration by Copper and Manganese Compounds.** E. C. B. Bott and L. D. Gill. *Trans. Inst. Rubber Ind.*, 1943, 19, 53-58. The authors report an investigation into the effects of Cu and Mn compounds on the tensile strength of vulcanised rubber sheet, these agents being introduced as stearates in a typical mixing. It is found that small amounts of Cu have about twice the effect of the same amounts of Mn. The deteriorations per day (at 82° C. in the Geer oven), D (per cent. loss of strength, dumb-bell specimens) follow a square-root law for Cu,  $D = 0.32\sqrt{[Cu]}$ , and a straight-line law for Mn,  $D = 0.013[Mn]$ , where [Cu] and [Mn] are concentrations in parts per million. The highest concentrations tried were 0.06 per cent. of Cu and 0.08 per cent. of Mn. Anti-oxidants in the mixing gave reasonably good protection against the effects. C.

**Mildew and Rot Resistant Fabrics: Testing.** See Section 5C.

#### PATENTS

**Synthetic Resins: Application to Fabrics.** United States Rubber Co. B.P. 561,152 of 22/10/1942:8/5/1944 (Conv. 24/1/1942). A fabric is immersed in an aqueous bath containing particles of synthetic resin which have been agglomerated from the dispersed state to the form of flocs which are macroscopic and readily separable from the aqueous medium on standing and which are capable of depositing on the fabric on contact therewith, and the fabric is

maintained associated with the bath until at least part of the flocculated particles of synthetic resin have been deposited on the fabric. The bath contains sufficient stabilizer to prevent the resin flocs from completely coagulating into a coherent lump, but insufficient stabilizer to prevent the flocs from depositing on the fabric. A preferred method of preparing the bath comprises treating a resin dispersion with a monovalent salt of a strong acid in the presence of both clay and a protein, such as gelatin, and also a stabilizer for the agglomerates. C.

**Cloth Tentering and Cropping Range.** G. K. Seddon and H. Blakeley. B.P. 561,164 of 23/12/1942:8/5/1944. A wet piece of cloth after being scoured is passed through a tentering machine for drying and attached to a wrapper which has been threaded through a cropping machine either at the front or at the back of the tentering machine, the tentering, drying and cropping then proceeding as one combined operation. Details are given of an arrangement in which the wet piece of cloth, after being scoured, is passed over rollers which occupy an elevated position, through a piece guider that guides and centres the cloth in its passage to another roller over which it passes down to and under a pair of spaced rollers or rods underneath a platform, up and on to the pins of the tentering and drying machine and through the latter, the end of the piece of cloth after being dried in the tentering machine being sewn to a wrapper that has been threaded through a cropping machine provided with one or two rotary cutters. C.

**Dihydroxy Azo Dyes: Production.** J. R. Geigy A.-G. (Basle). B.P.561,228 of 3/11/1942:10/5/1944 (Conv. 4/11/1941 and 25/7/1942). Monoazo dyes are produced by coupling diazotised 6-nitro-2-amino-4-alkylphenols, of which the alkyl group contains at least three C atoms, with azo components containing at least one water-solubilising group and which in *o*-position to the coupling point bear a hydroxyl group. The presence of the nitro group in 6-position in conjunction with an alkyl group with at least three carbon atoms in 4-position results in surprisingly good fastness to light and enhances the suitability of the dyes for the single-bath chroming process. C.

**Cellulose Acetate Materials: Dyeing.** British Celanese Ltd. B.P.561,249 of 7/11/1942:11/5/1944 (Conv. 15/11/1941). Acetone-soluble cellulose acetate textile materials are dyed by mechanically impregnating them with a solution of a dye in 20-50 per cent. acetone. By this method it is possible to effect very rapid incorporation of dye in the material and to ensure extremely good penetration even of heavy or closely woven fabrics. When dyeing fabrics it is usually of advantage to follow this operation by a topping operation in an aqueous dye bath free from acetone. In the dyeing of staple fibre products, e.g. carded or drawn slivers or combed tops, it is usually possible to dispense with the aqueous topping operation. The process described is particularly useful for dyeing acetone-soluble cellulose acetate materials with insoluble direct dyes. C.

**Azo Dyes: Production.** Calico Printers' Association Ltd., A. Burawoy, Margaret G. Barclay and G. H. Thomson. B.P.561,302 of 30/10/1942:15/5/1944. Water-insoluble mono- and poly-azo dyes are made by reacting one or two molecules of a diazonium salt of an aromatic amine or amino azo compound which does not carry any additional water-solubilising group such as  $-\text{OH}$ ,  $-\text{COOH}$ ,  $-\text{SO}_3\text{H}$ , with a coupling component of the phenolic type having the general formula

in which Ar', Ar'' and Ar''' are substituted benzene residues which do not carry any additional water-solubilising group, and one or more of which have at least one coupling position free, and R' and R'' are hydrogen or hydrocarbon residues. On textile materials yellow, orange and brown shades are produced which are characterised by very good fastness to light and washing, and very good dischargeability by formaldehyde sulphonylates. The shades may be modified and further improved in fastness to light by after-treatment with metallic salts such as Cu, Co and Ni salts. C.

**Laminated Plastic Sheets: Production.** Dux Chemical Solutions Co. Ltd., C. A. Redfarn and F. W. Elliston-Erwood. B.P.561,351 of 11/11/1942:16/5/1944. In a process for the manufacture of fibrous sheets, such as cloth and paper, impregnated with phenol-aldehyde resins for the production of

laminated materials, the impregnation is effected without the addition of organic solvents with the preliminary condensation product which, whether dissolved in or separated from water, is liquid when cold, and the impregnated material is dried by blowing hot air streams into it on both sides while it is travelling. C.

**Woven Glass Fabric: Roughening and Rubber Coating.** Rubbaglas Ltd. and G. W. Betteridge. B.P.561,356 of 20/11/1942:16/5/1944. Woven glass fabric is roughened by treatment with an etching solution, such as hydrofluoric acid, or by blasting with sand or other abrasive materials. A rubber mix may then be applied to the fabric and vulcanized. The coated product is suitable for use as an electrical insulating material, as damp-course, or for the production of waterproof clothing. C.

**Wind- and Water-proof Pile Fabrics: Production.** W. I. Taylor and J. F. Levers. B.P.561,376 of 10/11/1942:17/5/1944. A process for the production of wind- and water-proof effect fabrics comprises impregnating the backing of a pile fabric, of which the pile comprises flat filaments of a cellulose derivative, with a synthetic hydrophobe coating material, and subjecting the fabric before or after impregnation of the backing to the crinkling action of a boiling aqueous medium. The coating material may be an alkyd resin or a derivative of polyvinyl alcohol or of polyacrylic or polymethacrylic acid, a synthetic rubber-like material, or a cellulose derivative. Thermo-setting synthetic resins may be applied from solution or dispersion in an organic solvent while in a partially condensed condition, and the treated fabrics may be subjected to heat in order to convert the resins into the thermoset insoluble state. Plasticisers, pigments, etc., may be incorporated in the coating compositions. C.

**Saponified Cellulose Ester Yarns and Fabrics: Treatment to Increase Capacity for Shrinking.** British Celanese Ltd. and W. J. Simpson. B.P.561,402 of 13/11/1942:18/5/1944. The shrinkage on drying of textile materials consisting of regenerated cellulose yarns which have been obtained by stretching and saponifying yarns made of an organic ester of cellulose, is improved by impregnating the materials with a solution containing between 30 and 75 per cent. by weight of a mercerising and shrinking base, neutralising the base immediately after impregnation, and then washing the yarns free from acid. The treatment not only imparts to the yarns the requisite capacity for shrinkage on drying, but also improves their extensibility. Yarns may be treated in unassociated form or in the form of fabric. The mercerising agent is preferably caustic soda and the acid dilute hydrochloric or sulphuric acid. C.

**Chromable Monoazo Wool Dyes: Production.** W. F. Beech, M. Mendoza and Imperial Chemical Industries Ltd. B.P.561,516 of 18/9/1942:23/5/1944. Chromable monoazo wool dyes are manufactured by coupling diazotised *o*-amino-phenol or -naphthol monosulphonic acids, which may carry simple substituents such as halogen and nitro, with a 1-(phenoxyphenyl)-3-(methyl or phenyl)-5-pyrazolone wherein the phenyl groups may carry as substituents halogen, alkyl or alkoxy, but are otherwise unsubstituted. These dyes are eminently suitable for application by the meta-chrome process and yield strong dyeings, ranging in shade from orange-brown to bluish red, and of good fastness to washing, milling, potting and light. C.

**Monoazo Wool Dyes: Production.** Sandoz Ltd. (Freiburg, Switzerland). B.P.561,622 of 17/6/1942:26/5/1944 (Conv. 11/7/1941). Monoazo dyes are obtained by coupling diazotised aminobenzenesulphonamides, in which one H atom of the sulphonamide group is replaced by an acetyl group, with 1-aryl-5-pyrazolone-sulphonic acids. The products dye wool from acid baths in pure greenish-yellow shades of excellent fastness to light. C.

**Pigmented Emulsions: Preparation.** Interchemical Corporation (New York). B.P.561,641 of 26/5/1941:30/5/1944 (Conv. 3/8/1940). A three-phase, pigmented, stable emulsion, for textile fabric decoration, consists of an aqueous phase, a phase comprising a pigmented resin-organic solvent aggregate and a phase comprising an organic composition which is not fully miscible with the aggregate, an emulsifying agent being present in the emulsion. It is desirable that the aqueous phase should constitute at least 20 per cent. by weight of the emulsion and it is also preferred that the organic composition phase has

less than 10 per cent. of non-volatile components by weight. The resin employed is a synthetic resin of the kind convertible by heat to a form which is insoluble in washing and/or dry cleaning agents. The organic composition is preferably a thin lacquer of low solids content, which is capable of diluting the pigmented lacquer phase when added in small quantities, but causes the formation of a phase comprising pigmented resin-solvent aggregates in the low solid lacquer when added in larger quantities. The three-phase emulsions may be made by mixing a pigmented lacquer and an unpigmented lacquer and then emulsifying the same with water, or emulsifying either of the lacquers with water and then adding the other lacquer, or emulsifying each lacquer separately with water and then mixing the resulting emulsions. The use of such three-phase emulsions in printing makes possible much finer printing, permits the use of cheap pigments, and smaller quantities of pigments, and avoids the after-treatment necessary with conventional printing pastes. C.

**Pigments: Application in Dyeing.** Interchemical Corporation (New York). B.P.561,642 of 26/5/1941:30/5/1944 (Conv. 3/8/1940). A method of pigment dyeing a fabric while avoiding migration of colour on drying, comprises saturating the fabric with a pigmented water-in-lacquer emulsion containing at least about 20 per cent. by weight of an inner aqueous phase, and an outer continuous lacquer phase, and drying the fabric. The emulsion contains a synthetic resin which is convertible by heat to a form that is insoluble in washing and/or dry cleaning agents, such as a urea-formaldehyde resin. The fabric may be saturated with a three-phase emulsion the outer phase of which is a solution consisting essentially of volatile solvent having dissolved therein an agent capable of forming a water-in-lacquer emulsion, and the inner phases of which comprise an aqueous phase containing at least 20 per cent. of water based on the total weight of the emulsion, and a pigmented complex of solvent and heat-convertible synthetic resin, the total binder content of the emulsion being not above 2.5 per cent. C.

**Anthraquinone Dyes: Production.** E. I. Du Pont de Nemours & Co. and W. Dettwyler. B.P.561,754 of 27/11/1942:2/6/1944. Dyes of the dianthrimide carbazole type which carry on one of the anthraquinone molecules the benzothioxanthone nucleus and on the second anthraquinone molecule a benzoylamino group attached in an  $\alpha$ -position are prepared by condensing 5-amino-2:1(S)anthraquinone-thioxanthone with 1-chloroanthraquinones which carry in one of the positions 4, 5 and 8 a benzoylamino group, and ring closing the resulting anthrimide by treatment with aluminium chloride in nitrobenzene or in pyridine, and, preferably, further treating the product with an oxidising agent, e.g. sodium dichromate. The products are vat dyes which dye in orange to red shades from the usual alkaline hydrosulphite vat by either the warm or the cold dyeing method. The dyeings or prints have very good fastness to light, chlorine and washing. C.

**Mothproofing Wool, etc.: Use of Amino Acid Amide Derivatives.** H. Martin and W. Stambach (to J. R. Geigy A.-G.). U.S.P.2,325,331 of 27/7/1943 (through *Chem. Abs.*, 1944, 38, 496). 2 mol. dimethylamine or other primary, secondary or tertiary amine of the aliphatic, araliphatic, hydroaromatic or benzene series is treated in water with a compound of general formula (halogen-CH<sub>2</sub>-CO-NH)<sub>2</sub>X (X=an aromatic radical containing >1 benzene ring). The products are used for mothproofing. W.

**Sulphonated Hydrocarbon Textile Treating Composition.** E. I. Du Pont de Nemours & Co. U.S.P.2,334,764. A composition for treating textiles consists of 50-90 per cent. of a saturated hydrocarbon having at least 16 C atoms and 50-100 per cent. of an alkali salt of a sulphonic acid obtained by exposing a mixture of the hydrocarbon with sulphur dioxide and chlorine to actinic light until 10-50 per cent. has been converted into the sulphonyl chloride and then hydrolizing the product with an alkali metal hydroxide. C.

**Stearamide Wetting and Softening Bath.** Alrose Chemical Co. U.S.P. 2,334,852. (a) A textile wetting bath comprises a dilute aqueous solution of an amide formed between 1 part of stearic acid and 1.2-2.0 parts of 2-amino-2-ethyl-1:3-propanediol. (b) A textile softening bath comprises a dilute solution of a salt of an amide formed between 1 part of stearic acid and 1.2-2.0 parts of tris-(hydroxymethyl)-aminomethane, NH<sub>2</sub>·C(CH<sub>2</sub>·OH)<sub>3</sub>. C.

**Alkaline Cellulose Solution: Application in Finishing.** Lilienfeld Patents Inc. U.S.P.2,335,126. An intimate suspension of degraded cellulose in caustic alkali is applied to fabric and the degraded cellulose is then coagulated. The degree of degradation is defined as that secured by heating comminuted pulp for viscose with 20 times its weight of 0.5 per cent. hydrochloric acid for 2-12 hours and then washing the solid residue. C.

**Ornamental Plastic Coated Fabric.** M. H. Storch (assignor to H. E. Darr, New York). U.S.P.2,335,222. Textile fabric is impregnated with a plastic material which is arranged to form a thin, flexible, waterproof film on the back and a series of ornamental protuberances on the face, so spaced that the finished fabric is flexible and capable of being stitched on a sewing machine. C.

**Aminodioxane Wetting Agent.** Commercial Solvents Corporation. U.S.P. 2,335,447. The claim is for capillary-active solutions of aminodioxanes,

in which X is cycloalkylidene, alkylidene, substituted cycloalkylidene or the group  $>\text{CR}_1\text{R}_2$ . C.

**Vinyl-Isocyanate Co-polymer Finishing Agent: Application.** E. I. Du Pont de Nemours & Co. U.S.P.2,335,582. Textiles are impregnated with a co-polymer of (a) a vinyl or vinylidene compound and (b) a 1-alkenyl isocyanate or aliphatic  $\alpha$ - $\beta$ -unsaturated acyl isocyanate (or isothiocyanate), and then heated at 70-200° C. C.

**Artificial Leather: Production.** Brown Co. (Berlin, N.H.). U.S.P.2,335,702. A water-laid felted mass of cellulose fibre is passed through a mixture of homogenized starch and rubber latex in which the starch comprises 10-50 per cent. of the total solid matter. C.

**Nitrocellulose-coated Dyed Fabric: Production.** E. I. Du Pont de Nemours & Co. U.S.P.2,335,739. Dyed fabric that would discolour nitrocellulose in contact with it is coated with a resistant mixed cellulose ester of a number of the lower fatty acids, before applying the outer coat of nitrocellulose. C.

**Sulphur Dye Printing Composition.** E. I. Du Pont de Nemours & Co. U.S.P. 2,335,905. The printing composition contains (1) a substantially pure sulphur dye, (2) a film-forming material and (3) a volatile organic solvent for (2). C.

**Plastic Cop Dyeing Tube.** Franklin Process Co. U.S.P.2,336,086. A cop tube for dyeing comprises a framework constructed from a strip of plastic-impregnated and -coated fibre, with longitudinal strands of fibre cemented to the framework. C.

**Textile Oil.** Ontario Research Foundation. U.S.P.2,336,087. The oil comprises 80-95 per cent. of a mineral oil (Saybolt Universal viscosity 50-250 seconds at 100° F.) and 20-5 per cent. of a partial ester of a naphthenic acid and a polyhydric alcohol. C.

**Wool Fabric: Reducing Felting and Shrinkage.** E. Faude (to Kammgarnspinnerei Stöhr & Co. A.-G.). D.R.P. 728,673 of 29/10/1942 (through *Chem. Abs.*, 1944, 38, 494). The fabric is treated with a solution of chlorosulphonic acid in an organic solvent, then with water followed by a dilute aqueous solution of sodium carbonate or ammonium hydroxide. W.

**Hair: Steeping for Use in the Hat, Felt and Similar Industries.** A. Volz and C. Riess (to Chem. Fabr. J. A. Benckiser G.m.b.H.). D.R.P. 731,577 of 14/1/1943 (through *Chem. Abs.*, 1944, 38, 652). The hair is steeped in an aqueous solution of phosphoric acid containing less water than orthophosphoric acid. An alkali, ammonium or amino salt of the acid may be used, in which case a subsequent treatment in dilute nitric acid follows. W.

**Animal Fibres: Improving Felting Properties.** H. Haakh (to I. G. Farbenind, A.-G.). D.R.P.731,871 of 21/1/1943 (through *Chem. Abs.*, 1944, 38, 652). Animal fibres are treated with compounds of multivalent metals and with hydroxyalkylated high-molecular aliphatic hydroxy compounds or hydroxy-alkylated phenols substituted in their nuclei by high-molecular hydrocarbons. W.

## 5—ANALYSIS, TESTING, GRADING AND DEFECTS

### (A)—FIBRES

**Controlled Temperature and Humidity Cabinet.** A. Gallenkamp & Co. Ltd. *J. Sci. Instruments*, 1944, 21, 90. A cabinet designed for humidity and temperature tests is built with double walls of asbestolite sheet with insulating material between. The single door hung on heavy hinges closes against a soft gasket by a spring catch. A window is double glazed, and has a small heater between the two sheets of armour-plate glass to prevent condensation. A direct driven fan circulates the air inside the cabinet; the air passes across the working space and returns behind false walls. Heaters and the outlet from a moisture generator are placed between the false walls so that hot moist air is rapidly dispersed throughout the cabinet. Conditions within the cabinet are controlled by a sensitive thermostat and by a hair hygrometer fitted with electric contacts. An end compartment contains a large water tank, moisture generator, fan motor and the electrical controls. A tank is fitted so that soft or distilled water can be used to prevent furring. The water feed to the moisture unit passes through a valve into a constant level tube, the flow being visible through a window in the control panel. The automatic control functions up to 50° C. and just under 100 per cent. R.H. The cabinet can be cooled if necessary, and drying agents used to reduce the humidity. For use above 50° C. the humidity controller has to be removed. To obtain saturation at any temperature the controls are changed so that the thermostat controls the temperature of the moisture unit, and the heaters are permanently off. By this means automatic control is obtained up to 75° C., with a humidity of over 95 per cent. R.H. Higher temperatures can be obtained safely at reduced humidities. C.

**Chain Polymer Fibres: X-Ray Studies.** I. Fankuchen and H. Mark. *J. Applied Physics*, 1944, 15, 364-370. Small-angle scattering of high polymers is studied under (a) scattering of randomly distributed spherical particles, the diameter of which is large as compared with the wave length, (b) scattering of rod-shaped particles, the axes of which are all parallel to the (fibre) axis of the sample, but the centres of which are randomly distributed in space, (c) scattering by spherical particles which are approximately in a closely packed arrangement, and (d) scattering by rod-shaped particles which are closely packed and all parallel to the fibre axis. Observations on highly orientated polymers, such as viscose rayon, cellulose acetate, nylon filaments, and highly stretched rubber bands are discussed. The study of small-angle scattering of orientated chain polymers indicates the existence of periodic or quasi-periodic heterogeneities perpendicular and (in some cases) parallel to the axis of stretch, which are of the order of magnitude between 50 and 300Å and apparently depend upon the conditions under which the fibres are formed. The application of an X-ray microtechnique to the examination of high-polymer fibres is described. A series of microdiagrams taken along a single filament of highly stretched viscose rayon shows rather distinct variations in the degree of orientation from point to point. Series of micro-X-ray diagrams are given showing the changes occurring in the centre and at the surface during the attenuation of a polyamide fibre during drawing. The diagrams show that the process of drawing leads to a homogeneous, crystallised, and highly orientated fibre. C.

**Cottonized Bast Fibre: Determination in Mixtures with Staple Fibre.** O. Viertel. *Kleppig's Textil-Z.*, 1941, 44, 772 (through *Chem. Zentr.*, 1941, ii, 1572-1573 and *Chem. Abstr.*, 1944, 38, 1883<sup>6</sup>). The method of Marschall, in which the staple fibre is dissolved by a mixture of formic acid and zinc chloride, can be carried out quickly, gives sufficiently accurate results and is suitable for practical plant control. The procedure is described in detail. The various grades of staple fibre differ in their rate of solution in the solvent mixture. C.

**Raw and Bleached Groundwood Pulps: Differentiation.** J. H. Graff. *Paper Trade J.*, 1944, 118, TAPPI, 133. In ultra-violet light sheets of unbleached groundwood pulps exhibited fluorescent colours varying from dark purple-drab to dark vinaceous-gray and a sample of bleached groundwood pulp gave a very light "vinaceous-gray" fluorescence. In mixtures, particularly with other types of fibres, this differentiation would be uncertain. The Loften-Merritt

stain, which is prepared by mixing 10 parts of 2 per cent. Malachite green, 20 parts of 1 per cent. fuchsin and 3 parts of 0.05N. hydrochloric acid, can be used for the microscopic differentiation of unbleached and bleached groundwoods. Unbleached groundwood is stained deep violet to pale violet, and commercial peroxide bleached groundwood amethyst violet to light Hortense violet. Tests with mixtures of known composition show that analyses can be made with a small percentage of error. Differences in colour obtained with the Loften-Merritt stain with unbleached and bleached pulps, and differences in the fluorescence of hand-sheets prepared from the pulps persisted after the pulps had been dried and stored for 16 months. C.

**Wool Fibre: Relation between Damage and Cystine Content.** E. Elöd, H. Nowotny and H. Zahn. *Kleppzig's Text. Z.*, 1942, 45, 663-672 (through *Chem. Zentr.*, 1943, 1, 112 and *Chem. Abs.*, 1944, 38, 871). Differently-treated wool yarns were tested for nitrogen, sulphur and cystine contents and resistance to tear. Damage caused by acid pre-treatments do not affect the cystine content; alkali and reducing treatments cause only slight damage, but produce considerable changes in cystine content. In bleaching, the extent of damage is approximately the same as the change in cystine. Cleavage of cystine causes only slight loss in strength, while the splitting of the peptide linkage causes extensive destruction. Most chemical treatments attack both cystine and the peptide linkage. There is no definite relation between cystine content and mechanical injury. W.

**Textile Fibres and Fabrics: Identification and Analysis.** *Dyer*, 1944, 91, 223-226, 265-266, 307-308, 343-344, 395-399. Fibres are classified according to their chemical composition and their suitability for various types of fabrics. Recognised methods are described for identifying fibres (including microscopic examination, appearance in ultra-violet light and reaction to various staining reagents), for determining impurities and finishing agents, and for estimating fibre composition in mixture fabrics. W.

#### (B)—YARNS

**American Rayon Yarns: Deniers and Filament Numbers.** H. R. Mauersberger. *Rayon Textile Monthly*, 1944, 25, 128-130. The author calls attention to the few recent changes in rayons on the American market and provides the following tables: (1) Deniers and filament numbers of rayon yarns now marketed by American producers, (2) Authentic table of deniers and filament numbers of American high-tenacity yarns, and (3) Rayon hosiery yarns produced in the United States. C.

**Rayon Crêpe Yarn: Contraction on Twisting.** Liberty Throwing Co., Inc. *Rayon Textile Monthly*, 1944, 25, 122-123. A previous table is revised. It gives the percentage contraction, resultant denier and yards per lb. consequent on twisting rayon yarns of 50, 75, 100, 125, 150, 200, 300 and 450 denier and the Du Pont Dull No. 7 novelty 200/8/3 yarn, the turns per inch being increased in steps from 15 to high crêpe twists. Most of the data are based on actual tests. C.

**Warp and Weft from Cloth: Testing.** Ethel L. Phelps, Helen M. Ward, Delphine van Houten and Barbara Bailey. *Rayon Textile Monthly*, 1944, 25, 125-127. A report is given of a direct comparison of results obtained for count, twist, breaking load and extension at break of warp and weft yarns (a) isolated for a sufficient length in the cloth just before fixing in the testing instrument, and (b) pulled down from the cloth and allowed to lie for at least 12 hours before testing. Method (a) conforms with Specification D39 (1939) of the American Society of Testing Materials, a revision of which is under consideration and gave rise to the investigation. The cloths examined were six cotton twill jeans, five cotton suitings and three weights of wool serge. The results are summarised in tables. *Count.* Isolating the yarns just before testing (method a) seems to give slightly higher values (especially with the jeans) than previous pulling down of the cloth (method b), but the differences are statistically significant in only a few instances. It made no difference to the results whether the 10-inch lengths were cut by the experienced worker against a ruler or obtained on a twist tester with the yarn under tension equivalent to 156 gm. divided by the count. *Twist.* Method a gave slightly higher values than b, especially in wefts, but again the differences were statistically significant in only a few instances. *Breaking load.* No significant differences between the

(a) and (b) results were found for cotton warps and wefts or for wool warps, but wool wefts gave significantly lower strength figures by method (b). *Extension at break*. Most of the results were significantly lower by method (b). On the whole, therefore, pulling down the cloth some hours before testing the yarns is not recommended. C.

**Laboratory Conditioning Apparatus.** V. S. Federov and E. G. Türk-Eigess. *Khlopchatobumazh. Prom.*, 1940, 10, No. 11-12, 25-26 (through *Chem. Zentr.*, 1941, ii, 2513 and *Chem. Abstr.*, 1944, 38, 1884<sup>2</sup>). The apparatus is a hermetically closed box in which the humidity desired can be brought about quickly and can be varied from 0-100 per cent. The apparatus is shown and described in detail. A table lists various chemicals which are used to produce the required degree of humidity. C.

#### (C)—FABRICS

**Coated Fabrics: Water Vapour Permeability.** J. T. Stearn and A. S. Cooper, Jr. *Amer. Dyes. Rept.*, 1944, 33, 150-156. The water-vapour permeability of coated fabrics is discussed. Coated fabrics may be obtained that transmit some water vapour though preventing the passage of liquid water even under hydrostatic pressure up to 50 cm. It is suggested that water-vapour transmission through the coated fabric must take place by absorption by the coating material as well as the fibre on the high-humidity side and evaporation from the other surface exposed to lower humidity. Measurements of the water-vapour permeability of coated fabrics are reported. Details are given of the method. A permeability cup is used with a saturated atmosphere over water in the cup and a surrounding atmosphere at 70° F. and 65 per cent. R.H. Possibilities of errors due to (a) lowering of the water level in the test cup, (b) lack of equilibrium conditions before the first weighing, (c) varying tautness of the cloth, (d) edge leakage at the seal, (e) changes in barometric pressure during the test, and (f) humidity gradients in and outside the coated cloth are discussed. The results of measurements on poplin coated with ethylcellulose and with a vinyl resin, which before coating had been given a water-repellent finish with Zelan, on desized poplin, and on commercially finished poplin and print cloth are tabulated. The data show that the coatings, which were sufficient to prevent the passage of liquid water under a head of 50 cm. pressure, reduced the water-vapour permeability of the poplin only 10 to 35 per cent., the cellulose derivative coating giving a higher permeability than the vinyl resin coating. C.

**Dyed Cotton Fabrics: Deterioration by Light.** F. I. Sadov and E. D. Gruzdeva. *Tekstil'naya Prom.*, 1941, No. 1, 48-52 (through *Khim. Referat. Zhur.*, 1941, 4, No. 9, 125 and *Chem. Abstr.*, 1944, 38, 1645<sup>9</sup>). Samples of cotton fabrics dyed with Gold-Yellow Bg.K Indigosol lost up to 84 per cent. of their initial strength on 3 months' insolation, and samples dyed with Vat Gold-Yellow ZhKh dyes or with Solanthrene Orange NR dyes lost up to 75 per cent. Under the same conditions Thioindigo Ruby Zh and Vat Red KKh had almost no effect on the photo-chemical decomposition of cellulose. Vat Blue and Chloroindanthrene Light Blue had a protective effect on the fabric. Dyes containing more heterocyclic nitrogen have a greater protective effect against light. C.

**Plastics Yarn Fabrics: Defects.** *Rayon Textile Monthly*, 1944, 25, 134-135. A dozen illustrations are given of typical defects in fabrics woven from plastics yarns (not specified), with suggestions for their avoidance. C.

**Sulphur Dyed Textile Materials: Accelerated Ageing Test.** American Association of Textile Chemists and Colorists. *Amer. Dyes. Rept.*, 1944, 33, 145-146. An accelerated ageing test for textile materials dyed with sulphur dyes is carried out in a conventional laboratory drying oven, uniformly heated and controlled to  $\pm 2^\circ \text{C}$ ., or in a steam ager equipped with controls for uniform steam flow and temperature. The oven test is carried on for six hours at  $135 \pm 2^\circ \text{C}$ . At the end of 1, 2, 3, 4 and 5 hours the ports or vents are closed and 20 c.c. of water added for each cubic foot of oven capacity. The vents are kept closed for five minutes, then opened and circulation resumed for the rest of the period. As an alternative the test specimens may be removed from the oven at the end of each hour and thoroughly humidified in an atmosphere of steam, then replaced in the oven. At the end of the six hours the specimens are removed

from the oven and placed in a conditioning room. In the steam ager test the specimens may be suspended while ageing, or may be tacked on frames, which are then placed in the ager, pyramid style, with the bottom baffle functioning as a support. The specimens are aged for 8 hours with saturated steam at 15 lb. pressure, or for 16 hours at 7½ lb. pressure. The samples are then removed and placed in a conditioning room. Breaking load tests are used to determine the degree of deterioration, although cuprammonium fluidity may be used if desired. C.

**Fabrics: Testing of Handle.** *A.S.T.M. Bull.*, 1944, No. 126, 43-45. Details are given of proposed methods for the evaluation of properties related to the handle of soft-finished woven fabrics. The tests involve the use of the Planoflex apparatus for measuring flexibility by means of the distortion angle, the Friction Meter for measuring surface smoothness in terms of the coefficient of kinetic friction, and the Compression Meter for measuring compressibility. A combination of the measurements made on the Planoflex apparatus and the Compression Meter gives a measure of the fullness of a woven fabric. C.

**Finished Fabrics: Stiffness; Effect of Humidity.** Lelia J. Winn and E. R. Schwartz. *Amer. Dyes. Rept.*, 1941, 30, 226-230, 238. Samples of a rayon fabric, tag cloth, mulle sheer and glazed chintz were tested at different humidities on the Drapeometer. Results are given in tables and in graphs showing chord length plotted against vertical distance from top. They show that stiffness increases as the relative humidity is lowered. The use of the Drapeometer is explained. In tests with this device a rectangular sample is hung with its top short side around a drape disc and measurements are made of the contour of the specimen at various distances from the top. C.

**Industrial and Protective Clothing: Standardization.** C. Kendall and H. B. Duffus. *Industrial Standardization*, 1944, 15, 25-28. The American Standards Association has published specifications for women's industrial clothing and specifications for protective occupational (safety) clothing. The former include specifications for aprons, jackets, skirts, wrap-around and coat-style dresses, slacks, dungarees, overalls and coveralls. A large range of sizes, with 1½ in. gradations in size, is specified, except in the case of aprons for which three or four sizes are specified according to type. Slacks, dungarees, etc., are to be made in short, regular and long lengths. Selection of the suitable type of clothing to be worn for a specific job remains the responsibility of the plant management. The standards make no attempt to specify the type of job for which the garment is intended. The safety clothing specifications relate to leather aprons, cape sleeves, bibs and leggings for use in welding operations, sand blasting, etc. These garments are to be made from chrome-tanned leather which remains soft and pliable under heat and is thick enough to prevent sparks from burning through. The standard for leather aprons provides for steel reinforcement when needed. C.

**Mildew-resistant Fabrics: Soil-suspension Test.** Margaret S. Furry. *Amer. Soc. Testing Materials: Symposium on Mildew Resistance*, 1943, p. 15-22. In the soil-suspension method of testing the mildew resistance of fabrics, sample strips are first washed under a gentle flow of running water for 24 hours, then immersed for 30 min. in a thin suspension containing 70 g. of soil to 250 ml. of distilled water, and then placed on glass cloth in a culture bottle containing a suitable culture medium and incubated at approximately 28° C. for 10 to 14 days. Changes in breaking load are determined. The results of tests using different types of soil are discussed. An untreated cotton duck inoculated with a soil composted from one-third sandy loam field soil, one-third well-rotted manure, and one-third muck soil was completely rotted within 14 days of incubation. Results are given of tests of fabrics treated with copper compounds, using three different culture media and glass cloth, soil-cotton-soil wicks and other types of supports for the samples. A method of evaluating the effectiveness of treatments in terms of a standard, e.g. cotton osnaburg treated with copper naphthenate so that it contains about 1 per cent. copper by weight on the fabric is explained. Results obtained by the soil suspension test are compared with results obtained by the pure culture test for mildew resistance using *Chaetomium globosum* as the inoculum. The soil-suspension method appears to be a more severe test and in addition differentiates between

different treatments. It shows that, as the copper content decreases, copper naphthenate gives better protection against rotting than a copper oleate and resinate mixture. C.

**Mildew-resistant Fabrics: Soil-suspension Test.** Margaret S. Furry and Marian Zametkin. *Amer. Dyes Rept.*, 1943, 32, 395-398. Details are given of a method of testing the effectiveness of mildew-resistant treatments on fabrics for outdoor use in which samples of the treated fabric are inoculated by immersion in a soil suspension and then incubated under controlled temperature and humidity conditions. The fabric is first washed under running water for 24 hours and then cut into strips which are immersed for 30 min. in a suspension of soil containing 70 g. of soil to 250 ml. of distilled water. Soil composted from one-third sandy loam field soil, one-third well-rotted manure, and one-third muck soil is used. Incubation is carried out in a culture bottle containing a suitable liquid culture medium, the sample being supported on a strip of glass fabric which also serves as a wick to draw up the culture medium. The effectiveness of the treatment is determined from the breaking strength of the inoculated test strips in comparison with that of the original treated fabric. Results can also be evaluated in terms of a standard. Notes are given on microorganisms which have been isolated from soil and their action on cotton fabric. Applications of the soil suspension test are discussed and results of tests of various treatments are tabulated. Treatments with copper naphthenate, cuprammonium hydroxide, lead acetate with potassium dichromate, and cutch or osage orange with copper sulphate and potassium dichromate were found to be effective on cotton osnaburg. C.

**Mildew- and Rot-resistant Textiles: Testing.** H. D. Barker, G. A. Greathouse and P. B. Marsh. *A.S.T.M. Bull.*, 1944, No. 126, 32-34 and *A.S.T.M. Symposium on Mildew Resistance*, 1943, p. 1-4. The problem of standardizing test methods for mildew- and rot-resistant treatments of textiles is critically discussed. It is pointed out that preventive treatments and appropriate methods should take into consideration expected service conditions, types of fabrics, fungicides that are available or practical to apply, supplementary waterproofing or flameproofing materials and other special considerations. The importance of considering expected service conditions is illustrated by a study of the inter-relationship of the various factors that may be involved in fabric deterioration. Unknown and uncontrollable factors in soil burial tests and differences in behaviour of different soils are discussed, and the opinion is expressed that in spite of their shortcomings soil contact tests have an appropriate place in the testing of treated fabrics that are expected to be exposed to soil contacts. It is suggested that in devising practical test procedures there arises a need for two distinct types of tests—evaluation tests and acceptance tests. Evaluation tests should determine (1) whether the proposed protective agent has fungicidal or fungistatic properties, (2) the degree of resistance the proposed protective agent has to leaching, photochemical action, ionic adsorption, and other weathering agencies that eventually reduce the concentration on the fabric to a value that will permit growth of deleterious micro-organisms, and (3) the amount of the protective agent that must be applied to the fabric to assure practical service life. Acceptance tests should be rapid and of a routine nature, and be capable of detecting spotty application or ascertaining that the kind and amount of desired preventive treatments have been applied. They should be sufficiently severe properly to rank commercial treatments with excesses of the treating agent. The possibility of substituting chemical for biological tests is mentioned. C.

#### (D)—OTHER MATERIALS

**Gauges: Use in Quality Control.** L. H. C. Tippet. *Engineer*, 1944, 177, 481-483. Quality control of mass-produced articles often depends on making precise measurements (e.g. of diameter) on small, representative samples. In some circumstances it would be more convenient to apply a gauge, but this requires a far larger sample. It is now shown that by setting the gauge to give a larger fraction of "defectives" than the usual "passing out" gauges, inspection work can in some circumstances be considerably simplified; for example, gauging on 20 articles may give at least as good control of the average, or variability, or both, as actual measurements on 10 articles. C.

**Paper and Paperboard: Determination of Wet Tensile Breaking Strength.** Technical Association of the Pulp and Paper Industry. *Paper Trade J.*, 1944, 118, TAPPI, 143-144. A revision of TAPPI Tentative Standard T 456 m-42 is presented. The test is made in accordance with the procedure given in TAPPI Standard T 404-m. The Finch device, which is briefly described, is used for wetting tissue papers, paper towels, and other papers that are difficult to handle when wet. Materials that can be handled without difficulty when wet, and paperboards, are immersed in a shallow dish of liquid for a predetermined time. Ultimate wet strength is defined as the strength of the material after complete saturation with a liquid, and normal wet strength as the strength of the material after it has been wetted to an extent comparable with conditions of normal use. C.

## 7.—LAUNDERING AND DRY-CLEANING.

### (A)—CLEANING

**Clothing: Hot Air Disinfection.** W. Schmidt. *Z. Hyg. u. Infektionskr.*, 1943, 124, 606-614 (through *Bull. Hygiene*, 1944, 19, 309). Steam damages fabrics and particularly leather and furs; hot air, if efficient, would therefore be preferable. Two forms of apparatus are on the market in Germany, both intended to work at a temperature of about 100° C., and designed therefore to destroy only non-sporing micro-organisms. One is an oven in which clothing, etc., can be placed, and the other an oil-burning stove for raising the temperature of an entire room to this point. Both contrivances have been tested up to a temperature of 110° C., with bacteria dried on pieces of linen as test objects. Although they destroyed cultures of streptococci, staphylococci and *Bact. coli*, they failed to sterilize streptococcal or staphylococcal pus or faeces. It therefore appears that such treatment is likely to be unreliable for disinfecting naturally infected materials. C.

**Soap Solutions: pH and Detergent Effect.** M. Dole. *Amer. Dyes Rept.*, 1941, 30, 231-238. The significance of pH, electrometric and colorimetric methods of measuring pH, and glass electrodes for pH measurements are discussed. Curves are given showing the effects of alkaline builders such as sodium hydroxide, phosphate, carbonate, and borate on the pH of soap solutions, the variation in surface tension and in contact angle on paraffin of sodium oleate solutions with concentration and pH, and the variation in detergent power (as measured by changes in brightness of samples after washing) with pH of soap solutions containing builders. Explanations of the observed variations are suggested. The data indicate a definite relationship between pH and detergency, and that the total alkaline capacity of a solution, which can be measured only by titration, is also important. C.

**Dry Cleaning: Odours and Other Troubles.** P. C. Trimble. *Starchroom Ldy. J.*, 1944, May, 78, 82, 84, 86. A collection of springtime notes on avoiding odours in cleaned garments, the use of puff irons in finishing furniture covers, cleaning of suede jackets, the tumbling of woollens after spotting, production efficiency, leaking gaskets in distillation plant and the dry cleaning of greasy table linen. La.

**Dry Cleaning Solvent Mixtures: Separation Methods.** O. C. Cessna. *Ldy. & Dry Cleaning J. of Canada*, 1944, June, 16, 18. Impure solvent to be used in a dry cleaning machine may need filtration, distillation or decantation before or after distillation, according to the nature of the impurities. La.

**Dry Cleaning: Problem of Shrinkage.** *Ldy. Age*, 1944, May, 52, 54. The four primary factors affecting the shrinkage of woollen garments in dry cleaning are moisture, mechanical action, heat and alkali. La.

### PATENTS

**Peptone: Use for Washing Textiles.** A. Nordfeldt (Strangnas, Sweden). B.P. 561,542 of 20/3/1942:24/5/1944 (Conv. 4/3/1941). Textile materials can be washed with aqueous solutions of peptone. Such solutions have a cleaning action similar to that of soap solutions and are free from the drawbacks arising from the presence of free alkali and fatty acid in soap solutions. For cleaning cotton, linen, rayon and similar fabrics, it is advisable to employ peptonized water for a preliminary washing, by which a considerable portion of the dirt is

washed out, and a subsequent treatment with soap or other alkaline preparations which are then needed only in reduced quantity. C.

**Improvements in or Relating to Washing Machines.** British Thomson-Houston Co. Ltd. B.P.562,372. Conv. (U.S.) 24/7/41. Appl. (U.K.) 22/7/42. Acc. (U.K.) 29/6/44. The invention relates to washing machines of the type in which clothes are washed and centrifugally dried in a rotatable clothes receptacle, the object being to provide an improved construction for controlling the water supply level. One typical machine fitted with this device contains a rotatable clothes receptacle, from which the liquor overflows into the casing, a valve-controlled water supply conduit discharging into the receptacle, a hydraulic pressure operator for closing the valve, a bleeder conduit leading from the water supply conduit to the hydraulic operator, a by-pass conduit leading from the bleeder conduit for relieving the pressure in the hydraulic operator, and means responsive to the liquid level in the casing for closing the by-pass conduit. Another machine of the same type is provided with a valve biased to its closed position, a latch for holding the valve in the open position, and a hydraulic pressure operator for releasing the latch. La.

**Carbohydrate and Synthetic Surface-active Agent Washing Compounds.** J. Nüsslein and K. Pauser (Frankfort-on-Main); vested in the U.S. Alien Property Custodian). U.S.P.2,335,194. The washing compounds claimed comprise 90-70 parts of water-soluble derivatives of cellulose, starch and other polyoses with ether-like bound hydrocarbon radicals substituted by hydrophilic groups, and 10-30 parts of a non-hydrolyzing surface-active agent (selected from a wide range) the amount of which would not of itself be sufficient to effect washing. C.

## 8—BUILDING AND ENGINEERING

### (A)—CONSTRUCTION AND MAINTENANCE OF BUILDINGS AND PLANT

**Metals: Inspection and Testing.** J. E. Garside. *Engineer*, 1944, 177, 459-462, 478-9, 498-500. A useful summary is given of methods for the inspection of metallic materials under the headings:—(1) *Chemical composition*: (a) examination of colour, spark, magnetic and density tests, spectroscopy and acoustical tests; (b) chemical and electrographic analysis. (2) *Mechanical properties*: (a) hardness; (b) tensile, transverse, torsion, bending, impact and fatigue tests; (c) cupping tests; (d) damping capacity tests; (e) static or hydraulic tests. (3) *Determination of wall thickness and coating thickness*: Magnetic and electrical conductivity methods. (4) *Detection of surface defects*: (a) immersion tests, (b) fluorescence methods, (c) ferrographic method. (5) *Detection of unsound material*: (a) density, magnetic, conductivity and acoustical methods, (b) radiology. (6) *Determination of structure*: (a) etching, sulphur and phosphorus printing, detection of oxide inclusions, examination of fracture, and (b) microscopic and X-ray diffraction methods. The following tables are included: (1) Physical test data for irons, steels, nickel alloys, brass, bronzes, copper, aluminium, magnesium alloy, lead and solders. (2) Methods for determining Al, C, Cr, Pb, Mn, Mo, Ni, P, Si and S and the precision attainable. (3) Chemical and spot tests for the same materials as in Table 1. C.

**Wood: Effect of Heat on Strength.** P. H. Sulzberger (Forest Products Research Laboratory). *Engineering*, 1944, 157, 478. A preliminary report is given of an investigation of the effect of temperature ( $-10$  to  $+60^{\circ}\text{C.}$ ) on the mechanical properties of certain timbers and plywood at a moisture content of 15 per cent. Strength and most other properties investigated decreased with increased temperature. Toughness appeared to increase in some species and the deflection at failure in static bending increased considerably in all species. C.

**Wood Products: Uses.** "Times" Trade & Engineering, 1944, 55, May, p. 10 and 13. (1) The varied uses of wood, the need for future economy in use, the disposal of wood waste, the chemistry of wood, wood cellulose pulps for the paper and rayon industries, and the use of lignin as a plastic are briefly discussed. (2) Tests have shown that lignin extract, an abundant by-product of the pulp and paper industry, can be used in road construction and that it adds substantially to the bearing capacity of a gravel surface and to its resistance to shearing. The lignin extract is mixed with gravel and clay and the mixture,

spread in layers not exceeding three inches is consolidated by means of multiple-tyre rollers. For an impervious and good wearing surface the mat thus obtained must be covered with asphalt or tar. The use of the lignin extract enables savings in gravel and asphalt to be made. C.

**Alloys: Resistance to High-Temperature Steam.** I. A. Rohrig, R. M. Van Duzer and C. H. Fellows. *Amer. Soc. Mechanical Engineers, Preprint*, Nov.-Dec., 1943, 12 pp. (through *Nickel Bull.*, 1944, 17, 69-74). Specimens of various alloys were exposed, under operating conditions, inside a high-temperature steam line, being subjected to a steam atmosphere of 380 lb. per sq. in. at temperatures of 925° and 1100° F. (495° and 595° C.). Periods of exposure varied from 4,000 to 16,000 hours. Periodic determinations were made of changes in weight, hardness and structure. Details are given of the procedure and the superheater and pipe system used, and results are presented in tables. Charts showing penetration-corrosion, and photo-micrographs are also given. The results show that, in general, ferrous alloys containing high percentages of chromium alone are corrosion-resistant in steam at 1100° F. Ferrous alloys containing high percentages of chromium and nickel are also resistant at 1100° F. The non-ferrous materials tested were not so resistant to high-temperature steam as the high-alloy ferrous materials. At 1100° F. significant differences were observed between the rates of corrosion of carbon steels and of medium- or low-alloy steels: at 925° F. only a slight difference was found. At both temperatures many steels of a relatively low alloy content compare favourably in corrosion-resisting quality with steels in the medium-alloy group (e.g. 0.5 per cent. molybdenum steel with 5 per cent. chromium steel). The ability of a material to retain an adherent protective scale is an important factor in determining its resistance to attack by high temperature steam. Loss in weight of carbon steel under exposure to steam at 1100° F. continues for prolonged periods at a high rate, but the corrosion rate of alloyed materials slows down with increasing time of exposure. C.

**Alloy Steels: Resistance to High-Temperature Steam.** G. A. Hawkins, J. T. Agnew and H. L. Solberg. *Amer. Soc. Mechanical Engineers, Preprint* 10, Nov.-Dec., 1943, 4 pp. (through *Nickel Bull.*, 1944, 17, 68-69). Specimens of steel with sand-blasted surfaces were exposed to steam in an unstressed condition and the loss in weight determined. The results, together with results of previous investigations, show that all the steels tested, with the exception of the 25/20, 25/15/2, 21 per cent. chromium and 27 per cent. chromium specimens start to corrode rapidly at some temperature below 1675° F. (912° C.). After the break occurs, the rise in corrosion rate is much more rapid for the steel containing 12 per cent. chromium and the 18/8 stainless steel than for steels containing less chromium. The temperature at which rapid corrosion begins rises with the chromium content. Analysis of various layers of scale formed on chromium-molybdenum steels indicates that resistance to steam-oxidation is due to a thin and very dense tightly-adhering inner layer of scale, and a dense middle layer, which contains a higher concentration of the alloying elements than is present in the basis steel. The alloying elements diffuse outwards and the oxygen diffuses inwards, the combined effect causing the formation of the dense protective inner layer. The results confirm the conclusion drawn in earlier investigations, that the chromium content of a steel is a major factor in controlling its resistance to attack by high-temperature steam. Some empirical equations are presented for use in computing the amount of corrosion produced for the various steels in 500 hours at temperatures within the test range. C.

**Aluminium, Zinc and Zinc Alloy: Reactivity with Electrolytes.** J. V. Petrocelli and A. Phillips. *Electrochem. Soc. Preprint*, 1944, 85, No. 6, 51-70. An account is given of a study of the electrochemical behaviour of aluminium, zinc, and a zinc base die-casting alloy and its constituents. The changes with time of the electrode potentials were recorded and polarization measurements were carried out in solutions representing those used in electrodeposition practice. The corrosion of aluminium, zinc, and their alloys appear to be largely electrochemical in nature. The corrosion current on pure aluminium and pure zinc was determined by a cathodic polarization method and checked by weight loss measurements. Many couples of the individual metals concerned were

studied and the interaction currents determined. Polarization studies on composite electrodes showed how the current densities could be distributed on heterogeneous surfaces. C.

**Chemical Plant Cements: Properties and Applications.** R. Ward. *Industrial Chemist*, 1944, 20, 71-74, 201-204, 253-256, 283-288. A useful review is given of the various types of hydraulic cements, acid-resisting cements based on soluble silicates, rubber latex and resin cements, and lutes used in the construction of chemical plant, their properties, mixing and working conditions. C.

**Electrical Insulating Materials: Properties.** T. F. Wall. *Engineering*, 1944, 157, 482-483. The molecular structure of insulating materials is discussed and the properties of various synthetic materials are compared with those of natural products, such as paraffin, amber, wood, cotton, silk and rubber. The properties and uses of polyethylene, polystyrene (Trolitul), polyvinyl chloride (Igelit), polymerised iso-butylene (Oppanol), synthetic rubbers (Buna and Perbuna), and polyamide materials (Perlonseide) are briefly described. C.

**Metals: Corrosion Mechanism.** R. M. Burns. *A.S.T.M. Bull.*, 1944, No. 126, 17-20. A discussion of the electrochemical nature of corrosion, the application of electromotive force series, the formation of protective films, the influence of electrode polarization, the practical application of polarization curves, and the electrolytic nature of oxidation and tarnish. C.

**Metals: Galvanic Corrosion.** R. H. Brown. *A.S.T.M. Bull.*, 1944, No. 126, 21-26. The nature of galvanic corrosion is explained and its dependence on such factors as potential difference, polarization, current distribution, and resistance of both the corrosive environment and the metallic circuit, is studied. Methods of reducing galvanic corrosion by (1) more careful selection of alloys, (2) insulation of contacting alloys, (3) painting, and (4) cathodic protection are briefly discussed. C.

**Reinforced Plastics: Impact Strength.** P. M. Field. *Modern Plastics*, 1944, 21, No. 8, 123-125, 162. Tests were made on notched Izod specimens of phenol-formaldehyde and other resin materials reinforced with cotton, paper, asbestos, wood or glass, at room, high ( $+160^{\circ}\text{F.}$ ) and low ( $-70^{\circ}\text{F.}$ ) temperatures. Results are shown in tables and graphs. The strongest material tested was a glass- and cotton-reinforced phenolic resin which had an impact strength at room temperature of 22.5 and 18.0 ft. lb. per in. for face and edgewise impact, respectively. This exceeds the value for cast magnesium (9.5) and cast aluminium alloy (4.3), and is of the same order of magnitude as extruded magnesium (21.0) and rolled 24ST aluminium alloy (20). The next best materials were a moulded cord-reinforced phenolic and a low-pressure fabric-base phenolic. A phenol-formaldehyde resin reinforced with Mitscherlich (spruce sulphite) paper exhibited very poor edgewise strength. Investigations of the relationship between single blow and repeated blow impact strength have shown that for some thermoplastic materials, the impact fatigue strength is as low as 3.6 per cent. of the single-blow impact strength. For reinforced phenolic materials the value is approximately 50 per cent. For most of the materials the strength is greater at elevated temperature and lower at reduced temperature, but this trend is reversed in the case of glass-reinforced material. All laminated materials are better under facewise than under edgewise impact. C.

**Repair of Machinery.** W. F. Schaphorst. *Amer. Dyestuffs Reporter*, 1943, 32, 378. It is stated that it is unlawful to repair patented parts of machinery without permission of the patentee. La.

**Unusual Maintenance.** J. G. Berger. *Starchroom Ldy. J.*, 1944, Jan. 15th, 70. Unusual maintenance jobs include repair of damaged wood or metal parts (the latter by welding or spraying) washing machines, hydros, electric wiring and so on. Twelve points on boiler operation and nine on generator sets are enumerated. Other plant mentioned includes water heaters, reclaimers, traps, valves, pipes, electric motors and the importance of regular inspection and keeping of records is emphasised. La.

**Motor Maintenance.** R. R. Stodz and L. E. Markle. *Starchroom Ldy. J.*, 1944, March 15th, 66, 68, 70, etc. An article on motor maintenance by two members of the staff of the Westinghouse Electric & Manufacturing Co.

Starters and controllers should always be correctly matched to the motors and machines they control. The article is illustrated with a number of photographs showing steps in the maintenance and repair of contactors and switchgear and a chart for checking starter trouble is given. Contact pressure, worn and burnt contacts, lubrication, shunts, coils, dirt, dashpots and so on are discussed. La.

#### (C)—STEAM RAISING AND POWER SUPPLY

**Water Tube Boilers: Heat-transfer Calculations.** E. F. Lype. *Mechanical Engineering*, 1944, 66, 254-256. Two charts from which the value of the coefficient of heat transfer from gas to tube wall can be obtained for either staggered or in-line tube arrangements, and for any given value of the tube spacing, tube diameter, gas velocity, and mean film temperature, are presented and their use is illustrated by examples. C.

**Fuel Efficiency.** Ministry of Fuel and Power: Fuel Efficiency Committee. *Fuel Efficiency Bull.*, Nos. 25-30, 1943-1944. These bulletins deal with steam for process and heating, peak steam demands, control of air for combustion, flash steam and vapour recovery, industrial use of compressed air, and unorthodox use of economisers. W.

**Water Treatment.** S. H. Wellington. *Text. J. Australia*, 1944, 18, 460-466. Types of water, methods of treatment, and uses for steam raising, and for scouring, bleaching, dyeing and effluent treatment are discussed, with particular reference to the Australian textile industry. W.

**Smoke Abatement.** N. T. Pef. *Ldy. Age*, 1944, March, 55. Smoke abatement will be increasingly important after the war, although all causes of this trouble are not known. Among those which can be dealt with are deficiency of air, improper air mixing, forced firing, condition of grates and furnaces, kind of coal, and suggestions for their correction is given. La.

**Packings and Efficiency.** F. D. Mosher. *Ldy. Age*, 1944, March, 60. The handling, preparation of packing and work, and general installation of packings of various kinds are discussed together with the removal of old material and inferences to be drawn from its condition, e.g. distortion may mean lack of alignment and so on. La.

**Gasket Maintenance.** F. D. Mosher. *Ldy. Age*, 1944, Feb., 43. Wherever there is piping carrying fluids, gaskets and packing are important maintenance items. The effects of bad or improper packing and the choice of suitable packings for various purposes are considered. La.

**Burning Low Grade Fuel.** F. D. Mosher. *Ldy. Age*, 1944, April, 51. In considering the efficient burning of low grade fuel the following aspects are discussed: Overfire air jets to avoid smoke; air preheating; wetting and mixing; firing technique; installation of forced draught; ash removal; keeping fuel bed cool; automatic stokers. La.

#### (D)—POWER TRANSMISSION

**Belt Dressings: Composition and Use.** E. E. Halls. *Industrial Chemist*, 1944, 20, 241-244. Types of belts and their cleaning and maintenance are discussed. The characteristics required in a belt dressing are described. Formulae for various dressing compounds are given together with brief notes on the methods of preparation and application. C.

**Wire Ropes: Construction and Mechanical Properties.** N. Whincup. *Engineer*, 1944, 177, 405-6, 426-7. A concise account is given of the construction of various types of wire ropes (including crane and hoist ropes), the minimum sizes of pulleys and drums commensurate with the bending stresses, what to specify when purchasing a wire rope, and factors of safety. C.

**Transmission Belt Dressings: Composition.** K. Micksch. *Gummi-Ztg.*, 1941, 55, 326-327 (through *Chem. Zentr.*, 1941, ii, 838 and *Chem. Abstr.*, 1944, 38, 1814<sup>6</sup>). A review and discussion of the proper treatment and upkeep of transmission belts. Belt dressings usually are composed of train oil, tallow or degreas. Mineral oils or fat oils (olive oil, castor oil, etc.) also may be added, but not over 5 per cent. should be present. A high rosin content should be regarded as an adulteration. C.

**Group or Individual Drive.** J. G. Berger. *Starchroom Ldy. J.*, 1941, October 15th, 102, 104. A discussion of the relative merits of group and individual drives and the factors to be considered when planning a changeover from either method to the other. La.

(F)—LIGHTING

**Cotton Mills: Lighting.** J. W. Howell. *Trans. Illum. Eng. Soc.* (London), 1943, 8, 75-96. The various processes carried out in cotton mills and their lighting requirements, and suitable lighting systems, are discussed. For the preliminary processes 6 to 10 ft. c. are required. Spinning, twisting, fancy doubling, winding, slashing and dressing, packing, weaving (grey cloth) and inspection (grey cloth) require 10 to 15 ft. c., warping, weaving (light colours), and mending require 15 to 25 ft. c., and weaving (dark colours) and perching, 25 to 50 ft. c. Installation costs, the maintenance of lighting equipment, the influence of walls, windows and ceilings, and the desirability of systematic lamp replacement are discussed. Results are given of tests showing increases in output, quality and profits secured by improvements of lighting in beam warping and weaving processes. C.

**Dufton Window Scale: Application.** A. F. Dufton. *Trans. Illum. Eng. Soc.* (London), 1943, 8, 61. The problem of estimating the area of window necessary to provide a given daylight-factor at a point, on the working plane, opposite the centre of the window, may be resolved in terms of the daylight factor per foot width of window, a quantity which is readily determined from a drawing. The method is briefly explained and a scale designed for use in such determinations is shown. C.

**Fluorescent Lighting Fixtures: Design.** *Modern Plastics*, 1944, 21, No. 8, 98-100. The rapid growth in the use of fluorescent lighting in industrial and commercial establishments is briefly discussed and it is pointed out that for domestic and some commercial uses modifications in colour and improvements in the design of fixtures are desirable. Fixtures incorporating (1) louvres of extruded cellulose acetate strips, (2) corrugated cellulose acetate sheet resting on glass rods slipped through moulded acetate rings, and (3) interwoven cellulose acetate strips attached to a frame fabricated of extruded acetate moulding are discussed. Photographs and blue prints are given. The advantages of cellulose acetate for such constructions are pointed out. C.

**Lighting Code Proposals.** H. C. Weston. *Trans. Illum. Eng. Soc.* (London), 1943, 8, 17-39. An attempt is made to apply some of the results of recent research on the relation between illumination and size of work, and the effect of brightness contrast, to the reconstruction of the Illuminating Engineering Society's code of illumination values on a more satisfactory basis. Satisfactory illumination and considerations governing the selection of a performance standard are discussed and it is suggested that recommended illuminations should be adequate to permit a performance of visual tasks which is of the order of 90 per cent. of the maximum possible at any higher illumination. This is subject to a minimum recommended value, applicable however crude or easy the visual task. Otherwise code illuminations are those necessary on the work itself, though their effectiveness is conditional upon general illumination to secure a suitable ratio of environmental to work brightness. It is suggested that the lower limit of the range could remain at its present value of 2 ft. c. The upper limit and the division of the range are discussed, and the need for a logarithmic scale is pointed out. A range consisting of thirteen effectively different illuminations, forming a series whose common ratio is 1.414 is presented. It may be divided into six sub-ranges, whose limits have a common ratio of 2, if it is desired to classify tasks on a broader basis. These illuminations are related to the size of detail involved in the visual task, and apply only when the contrast inherent in the work is the best possible. Correction for other conditions of contrast is discussed. A formula for computing the working illumination required and a graph from which the required illumination can be read are given. The agreement to be expected between the computed illuminations and current "good practice," and the application of the code are discussed. A report is given of discussions of this paper. C.

**Lighting Systems: Numerical Assessment of Effectiveness.** (1) W. D. Wright. (2) K. J. W. Craik. (3) Sheila J. Macpherson. (4) W. S. Stiles.

*Trans. Illum. Eng. Soc.* (London), 1943, 8, 43-58. Short papers are presented on the numerical assessment of the effectiveness of lighting by methods based on (1) subjective brightness measurements, (2) visual acuity, (3) blinking rates and (4) visual thresholds, and a report is given of a discussion of the papers. C.

**Non-uniform Sky; Illumination from —.** P. Moon and D. E. Spencer. *Illum. Eng. Soc. Trans.* (N.Y.), 1942, 37, 707-726 (through *Building Sci. Abstr.*, 1943, 16, 143). Previous investigations of the illumination from the skies have been based on uniformity of sky brightness, which never occurs in nature. Such an assumption leads to large errors in calculations of the illumination of interiors. Expressions and curves for the calculation of daylight illumination from overcast skies have been developed by the authors which take into account the variation in sky brightness obtained experimentally. Formulae and curves are given also for the outdoor illumination on horizontal, vertical and sloping surfaces. Practical conclusions are drawn relating to the size of windows and depth of rooms of importance for improved uniformity of natural lighting in buildings. C.

#### (G)—HEATING, VENTILATION AND HUMIDIFICATION

**Air: Ultra-violet Disinfection.** A. Hollaender. *Amer. J. Public Health*, 1943, 33, 980-984 (through *Bull. Hygiene*, 1944, 19, 308). The use of ultra-violet light for the control of airborne infection is critically reviewed. The development of low-pressure mercury vapour lamps with glass or quartz envelopes which emit about 80 per cent. of their radiation at wave lengths of 2,537Å (very near to the maximum bacterial activity of ultra-violet light) has made available an easy and relatively cheap method for aerial disinfection. However, the optimum conditions for the effective use of ultra-violet light need to be more clearly defined. Bacteria have been found to be more sensitive in dry than in humid atmospheres, but this may be partly due to different methods of air sampling. No reliable data are available to indicate what is adequate irradiation for disinfection of the atmosphere. Most tests are carried out in a clean experimental chamber with moist or dry bacteria finely sprayed into the air and the results thus indicate only the minimum irradiation required under ideal conditions. The presence of gross particles, such as dust, interferes materially with the effectiveness of ultra-violet light. The apparatus used also varies. Some use an irradiated ceiling, others use screens of ultra-violet light to act as barriers between beds, and others use ultra-violet light in air ducts. The extension of ultra-violet light to schools at Philadelphia apparently reduced the incidence of measles and chickenpox among the children in the irradiated classrooms. Good results in preventing cross-infection in children's hospitals, particularly respiratory infection, have been reported, and ultra-violet light has also been used in surgical theatres to prevent airborne infection of the wound during prolonged operations. Precautions must be taken to protect staff against over-exposure. C.

**Atmospheric Humidity: Physiological Influence.** American Society of Heating and Ventilating Engineers. *Inst. Heat. Vent. Eng. J.*, 1942, 9, 369-376 (through *Building Sci. Abstr.*, 1943, 16, 141-142). The present state of information about the physiological aspects of air conditioning is reviewed with respect to the following problems involved:—(a) *Influence of atmospheric humidity in cool air upon heat losses from the human body.* Experimental evidence is adduced to show that there is no physiological basis for humidifying air at moderate or low temperatures on thermal grounds. Evaporative heat loss is small and the vapour pressure difference of a cool atmosphere under moist and dry conditions is relatively small compared with the vapour pressure at the surface of the hot skin. An increase of 20-25 per cent. R.H. is required to compensate for a 1° F. decrease in air temperature. (b) *Influence of atmospheric humidity in warm air upon heat losses from the human body.* In the zone of evaporative regulation (above 60° F. for a clothed subject doing active work in still air or above 85° F. for the unclothed subject at rest) relative humidity and evaporative cooling become vitally important factors in comfort conditions, being influenced by metabolic activity, clothing and rate of air movement. As atmospheric and radiational temperatures rise above the critical point, evaporative cooling and heat dissipation are mutually compensated by a well-balanced increase in sweat secretion. The upper limits

of evaporative heat regulation are set, in very hot and dry air, by cessation of sweat secretion, and in very moist air by failure of sweat to evaporate from the body surface; these limits are shown graphically for various temperatures, humidities and working conditions and their significance is discussed. (c) *Influence of atmospheric humidity upon the dryness of the membranes of the nose and throat.* The researches of Seeley have shown that the drying effect on the mucous membrane is related to the absolute humidity of the atmosphere. Further studies by Winslow, Hemington and Nelsbach have established that, in this process, there is a critical point at 0.4 in. atmospheric vapour pressure below which, at any temperature from 50°-80° F., the throat surface is very definitely dry. To control the influence of dry air on the mucous membranes would necessitate a relatively high vapour pressure corresponding at 70° F. to over 50 per cent. saturation. C.

**Hot Dry Atmospheres: Physiological Effects.** F. C. Houghten, C. Gutherlet and M. Ferderber. *Heating, Piping*, 1943, 15, 205-208 (through *Building Sci. Abstr.*, 1943, 16, 175). Observations were made over the effective temperature range 77.5° to 95° F. with relative humidities of 30 per cent. and less. The results are recorded graphically and discussed. For a given effective temperature, the increase in pulse rate and in body temperature of workers at R.H. 30 per cent. and lower show the same reaction as previously found for higher relative humidities. Body temperature rise at 30 per cent. R.H. correlated well with effective temperature, showing a consistent rise after 3 hours' exposure to effective temperatures above 85° F. with a measurable rise for conditions above 90° F.. It was also found that about 3° rise in the mean radiant temperature had about the same effect as 1° rise in the effective temperature. The present data also conclusively confirmed the earlier findings that a person is comfortable at a slightly higher effective temperature when standing and moving about at work than when seated at rest. C.

#### (H)—WATER PURIFICATION

**Sodium Hexametaphosphate: Stability.** M. Kehren. *Zellwolle, Kunstseide, Seide*, 1943, 48, 133-134 (through *Chem. Zentr.*, 1943, ii, 386 and *Chem. Abstr.*, 1944, 38, 1593<sup>4</sup>). Recent tests show that sodium hexametaphosphate is hydrolysed only slowly at temperatures up to 100° and in the region of greatest stability, neutral up to faintly alkaline; hence for textile technical purposes 70° should no longer be considered the limiting temperature. C.

#### PATENT

**Yarn Beam Transport Apparatus.** Atlantic States Motor Lines, Inc. U.S.P. 2,335,516/7/8. These inventions relate to modifications of a framework for mounting heavy beams of yarn (rayon tyre cord or warps) on two tiers on a lorry or truck. The flanges of the beams run on tracks and the framework includes means for scotching the beams and locking them together. C.

### 9—PURE SCIENCE

**Colloidal Solutions: Coagulation; Formation of Chain Aggregations.** K. Hoffmann. *Kolloid Z.*, 1943, 103, 161-163 (through *Chem. Abstr.*, 1944, 38, 1160<sup>9</sup>). Equations are derived to show that the chains formed during the coagulation of colloidal solutions are due primarily to electrostatic forces which disappear faster at the chain fronts than on the sides of the chains, so that additional particles will attach themselves to the front. A secondary force is the induced dipole moment which causes greater attraction at the front surfaces. C.

**Molecular Dispersions; Kinetics of Aggregations in —.** H. Umstätter. *Kolloid Z.*, 1943, 103, 150-159 (through *Chem. Abstr.*, 1944, 38, 1161<sup>5</sup>). The molecular weight determinations of polymers if based on viscosity measurements may give too high or too low values. This may be due to the presence of freely rotating atom groups on the molecules which in a liquid medium behave as if they were dissociated although bound chemically by valence forces. On the other hand there are molecules that form aggregations in a liquid phase even though not connected by valence forces. The study of these cases is the purpose of the kinetics of aggregations. Examples are given of aggregations found in binary mixtures of water with one of the following: methyl, ethyl, propyl or

allyl alcohol, nitric, sulphuric or acetic acid. Viscosity curves are given at various concentrations and temperatures. The viscosities are due in most cases not to the molecules but to the aggregations formed. The composition of these micelles varies with the temperature. In water and methyl alcohol the micelle consists at 0° of  $1\text{CH}_3\text{OH}$  and  $4\text{H}_2\text{O}$ , whilst at 30° it consists of  $1\text{CH}_3\text{OH}$  and  $3\text{H}_2\text{O}$ . C.

**Starches: Water Sorption.** L. Sair and W. R. Fetzer. *Ind. Eng. Chem.*, 1944, 36, 205-208. Sorption isotherms have been obtained for seven varieties of starch on samples subjected to intensive desiccation and also on unheated controls. From these data the starches can be divided into cereal, pith or root, and tuber groups. If the hydroxyl group is the point of attachment for water, the results indicate that potato or tuber starch has a higher percentage of free hydroxyl groups available for the attachment of water molecules than has either pith or root starch or cereal starch, that is, the degree of association of the starch types follows the order: cereal > root or pith > tuber. This association difference may be connected with the differences in the gelation properties of these starches. Differences in the extent of hysteresis were observed. Desiccation reduced the ability of the starches to retain water, the greatest effect being on tuber starches at high temperatures. The sorptive capacity of potato starch was reduced to a value similar to those found for cereal starches, without causing gelatinisation or injury of the granule, by treating the air-dried potato starch for 3 hours with steam at a pressure of 5 lb. per sq. in. This treatment produced changes in the X-ray pattern and the pasting characteristics of the potato starch. C.

**Industrial Viscometers.** Ruth N. Weltmann. *Interchemical Review*, 1943, 2, 43-52. The various types of viscometers are reviewed and their suitability for use with plastic and thixotropic materials is indicated. The advantages of rotational viscometers are pointed out and the manner in which the material is sheared in a rotational viscometer is explained. Plug flow, the end effect, and mechanical problems influencing the design of rotational viscometers are studied. The "Interchemical" rotational viscometer is described. The most important equations relating to the use of rotational viscometers are summarised. C.

**Cellulose Acetate: Viscosity and Molecular Weight.** S. Bezzi and U. Croatta. *Atti ist. Veneto sci.*, 1939-40, 99, 905-931 (through *Chem. Zentr.*, 1941, ii, 887-888 and *Chem. Abstr.*, 1944, 38, 1356). The different behaviours of cellulose triacetates prepared by the method of exhaustive acetylation have been ascribed by various authors to the difference in the size of the micelles or of the molecule (different degrees of acetolysis). The preparation and fractionation of cellulose triacetate and of cellobiose acetate are described. The viscosities and molecular weights were determined by different methods. It is concluded that the solutions studied in this work represent molecular and not micellar dispersions and that the differences are a result of differences in the degree of polymerisation (D.P.). There is no clearly defined relation between D.P. and solubility because the latter also depends upon other factors. The cryoscopic method cannot be used for the molecular weight determination of these acetates. The value of  $\eta_{sp}/c$  for each fraction increased with concentration, the more so the higher the initial value of  $\eta_{sp}/c$ , a behaviour which appears to be characteristic of thread-like polymers in molecular dispersion and seems to indicate that the dispersions of the products investigated are of this type. A characteristic for each substance was the value of  $\eta_{sp}/c$  extrapolated for  $c \rightarrow 0$ . The viscosity increased with increasing temperature of acetylation or, at the same temperature, with the time of reaction. The temperature coefficient of viscosity is not large, from which it follows that the high viscosity is to be ascribed to the size of the dispersed particles and not to their solvation. The differences in the viscosity of the different fractions are not large ( $\eta_{sp}/c$  for  $c \rightarrow 0$  varies from 6 to 10.5). That the solutions contain molecules and not micelles follows from the fact that the individual fractions always have the same viscosity, even in various solvents or after different treatments (e.g. after repeated precipitation from acetic acid with water, by which a part of the compound becomes insoluble in cold acetic acid. The molecular weight was determined by the osmometric method and by determination of the acetyl content.

The acetyl content was somewhat higher than that calculated for cellulose triacetate (44.8 per cent.), which is explained on the assumption that in the end groups of the chain molecules, four instead of three hydroxyl groups are acetylated. The molecular weight by the cryoscopic method is too low because of supercooling and of the delay in the separation of the solid phase. C.

**Polymer Solutions: Rigidities.** J. D. Ferry. *Ann. N.Y. Acad. Sci.*, 1943, 44, 313-327 (through *Sci. Abstr.*, 1944, 47 A, 39). Solutions of a linear polymer of high molecular weight in a solvent with which it is miscible in all proportions grade uniformly from viscous liquids through gelatinous or rubber-like consistencies to plastic solids. The theory of the mechanical properties of such solutions is discussed in terms of the simplest mechanical model, the Maxwell element. Several methods of determining the rigidities of solutions of polymers are described. The results of measurements of the rigidities of solutions of polybutene, polystyrene, polyvinyl chloride, and polymethyl methacrylate are reviewed. The mechanical properties are discussed in terms of polystyrene in xylene. A mechanical model is proposed which describes all the properties of the polystyrene-xylene system, and consists of elements which can be identified with molecular processes. C.

**Polystyrene: Thermoplastic Flow.** N. M. Foote. *Ind. Eng. Chem.*, 1944, 36, 244-248. Measurements were made, over a wide range of temperatures and under different applied stresses, of the rate of compression of disks of polystyrene in a parallel plate plastometer and of the length of flow into capillary tubes. Nomographs were devised for calculating the apparent viscosity from the observed data. The empirical equation giving apparent viscosities of polystyrene for low stresses as a function of absolute temperature is  $\ln \eta = (40,000/RT) - 30$ . At higher stresses much lower apparent viscosities were observed. Possible explanations of this behaviour are briefly discussed. C.

**Plastic Materials: Thermal Expansion.** R. F. Clash, Jr., and L. M. Rynkiewicz. *Ind. Eng. Chem.*, 1944, 36, 279-282. A simple dilatometer technique for determining the volume/temperature relations of plastics is described, and data are reported for a number of thermoplastic materials, including vinyl chloride-acetate, polyvinyl butyral and methacrylate resins and cellulose esters. Calculated cubical expansion coefficients below and above the observed transition temperatures are reported, and the effect of plasticizer addition on the expansion coefficients and transition temperatures is discussed. In general plasticizers cause a lowering of transition temperature and it is suggested that this lowering may be analogous to the lowering of the freezing point observed with solutions. Polyethylene shows expansion characteristics similar to those of paraffin wax and appreciably different from those observed for the other thermoplastics studied. C.

**Rubber Molecules: Statistical Strength.** L. R. G. Treloar. *Trans. Faraday Soc.*, 1944, 40, 109-116. The methods worked out for the determination of the statistical lengths of paraffin chains are applied to the more complex problem of the rubber molecule. Distribution functions covering lengths up to 98 per cent. of the fully extended length are given for chains corresponding to molecular weights up to 17,400. C.

**Silkworm and Moth: Radioactivity and Uranium Content.** J. Hoffmann. *Z. physiol. Chem.*, 1942, 276, 275-279 (through *Chem. Abstr.*, 1943, 37, 5496<sup>1</sup>). The dry mass of the moth consists chiefly of calcium phosphate. The body of the pupa, without the chitinous shell, contains  $2.4 \times 10^{-7}$  g. of U per gm., the chitin shell  $6.78 \times 10^{-6}$  g. and the silk shell  $7.84 \times 10^{-6}$  g. The highest concentration of uranium is in the pupa (insect and chitin). The developing insect body is exposed to the  $\alpha$ -,  $\beta$ - and  $\gamma$ -rays of uranium and the weaker  $\beta$ -rays of  $K^{41}$ . A high concentration of U in the silk gland is presumed. The silk shell of the cocoon, impermeable to water, must ionize the air between the silk and chitin shells. The resting pupa is subject to the radioactivity of the accumulating uranium. C.

**Alumina Fibre: Use as Chromatoscopic Adsorbent.** H. Wislicenus. *Kolloid Z.*, 1942, 100, 66-82 (through *Sci. Abstr.*, 1944, 47A, 61). A comparison is made between organic fibres and the inorganic alumina fibre. Natural fibres are too brittle, too bulky and not sufficiently elastic for use as adsorbent; specially

prepared fibres are required. The activation of the aluminium by mercury halides is similar for both kinds. The process of preparation of the fibres, their uses in adsorption measurements, and automatic adsorption apparatus, are described and illustrated. C.

**Solvent-resistant Fritted Resin Filters: Production.** H. Rudolph. *Kolloid Z.*, 1943, 103, 164-166 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1944, A:816). The method commonly used in manufacturing ceramic filters, i.e., softening the surface of granulated material by heat and pressing under conditions which produce porous structure, may be applied to thermoplastic materials, but the products have a limited resistance to heat. In the manufacture of Iganil (aniline-formaldehyde) and Luvikan (polyvinylcarbazole) filters the softening by heat is replaced by swelling in organic solvents. With suitable solvents, filters are obtained which are solvent-resistant and heat-resistant up to 180° C. A fibrous superpolyamide filter can be manufactured by dissolving the polymer, precipitating it by a non-solvent, and pressing the precipitate without application of heat. The material can also be dispersed after autoclave treatment in the presence of water and the dispersed material pressed under the application of heat. The superpolyamide filter thus obtained shows a very limited resistance to water. The material can, however, be rendered water-resistant by admixing paraphenylenediamine (Demosit). Superpolyamide filters are temperature-resistant up to 140-150° C. The fritting temperature (120-190° C.) of resin filters is lower than that required for ceramic filters (700-1200° C.) and it is not necessary to shape the resin material before fritting. Resin filters are characterised by high uniformity of pore size and distribution. C.

**Lead: Detection in Water and Fine Chemicals.** F. Feigl and N. Braile. *Analyst*, 1944, 69, 147-149. For the determination of traces of lead in water, sodium mercuric sulphide and ammonium chloride are added. The precipitate of mercuric sulphide which is formed acts as a collector for minute quantities of lead sulphide and is filtered off on a porcelain Gooch crucible, moistened with hydrogen peroxide, dried and gently ignited. Lead sulphate may be identified by the formation of red rhodizonate of lead on spotting with sodium rhodizonate and buffer solution. Details of the reagents and procedure are given. Under the specified conditions lead may be detected in 10 ml. of water at a dilution of 1 in 10 millions, or in 100 ml. at a dilution of 1 in 100 millions. The test takes about 20 min. Traces of lead in certain fine chemicals can be detected by dissolving samples in water and testing as for water. C.

**Ozone: Occurrence and Determination.** J. L. Edgar. *Discovery*, 1944, 5, 104-107, 114, 141-143, 155. A popular account of the discovery, occurrence and properties of ozone is followed by a discussion of methods for the measurement of the extremely minute quantities of ozone in the atmosphere, with special reference to the Dobson ozone spectrometer (1931), and the separation of ozone from nitrogen dioxide by condensation and distillation. The following figures are recorded for these gases in the atmosphere: London, O<sub>3</sub> 1.3, NO<sub>2</sub> 0.3; Kew O<sub>3</sub> 2.4, NO<sub>2</sub> 0.75; Southport, O<sub>3</sub> 2.3, parts per 100 million. C.

**Dimethylaniline: Determination in Mixtures with Aniline and Methylaniline.** J. Haslam. *Analyst*, 1944, 69, 141-145. A method for the rapid colorimetric determination of dimethylaniline (up to 20 per cent.) in mixtures with aniline and methylaniline involves acetylation, dissolution in water, and reaction with nitrous acid. The absorption of the solution of the yellow nitroso body produced is measured in a Spekker absorptiometer. For the determination of larger quantities, i.e., of the order of 60 per cent. of dimethylaniline, use may be made of the method of Blumrich and Bandel for the titration of weak organic bases with perchloric acid in glacial acetic acid solution. The mixture is first treated with acetic anhydride to acetylate the primary and secondary bases, then the acetylation product is dissolved in glacial acetic acid, and the dimethylaniline is titrated with perchloric acid in glacial acetic acid solution,  $\alpha$ -naphthol benzein being used as indicator. C.

**Cellulose: Nitration in Organic Solvents.** J. Desmaroux, R. Dalmon and Genevieve Petitpas. *C. r. Acad. Sci.*, 1941, 212, 396-398 (through *Chem. Zentr.*, 1941, ii, 1104-1105 and *Chem. Abstr.*, 1944, 38, 1637<sup>2</sup>). The nitrogen content resulting on nitrating cellulose in mixtures of anhydrous nitric acid with ether,

dichlorodiethyl ether, acetic acid, propyl alcohol, butyl alcohol, acetic anhydride, chloroform and phosphoric acid depends on the mixed acid ratio. The mixture with ether does not nitrate and is unstable. The mixtures with chlorine compounds and fatty acids yield nitration products, if the nitric acid content is in equimolecular proportion or greater, whereas the acetic anhydride ratio must be 1:3. Mixtures containing chloroform or phosphoric acid require only a low content of nitric acid. The conclusion is drawn that the nitrating ability of the nitric acid is influenced by the basicity of the added substance, and that the condition of the nitric acid molecule in the mixtures, should be investigated by physical methods (Raman effect, infra-red spectrum, etc.). C.

**Methylated Starch: Fission Products.** K. Hess, H. A. Schulze and B. Krajnc. *Ber. deut. chem. Ges.*, 1940, 73, [B] 1069-1076 (through *Brit. Chem. Physiol. Abstr.*, 1944, A II, 93). When methylated potato starch (40-41 per cent. methoxyl) is treated with sodium, liquid ammonia, and methyl iodide in anisole, the product contains usually about 44-45.5 per cent. of methoxyl; high methoxyl content is obtained only if not too much sodium is used, an excess causing back-hydrolysis. Methyl iodide-silver oxide similarly gives variable results up to 45.6 per cent. of methoxyl. Hydrolysis of a product containing 45.55 per cent. of methoxyl gives methyl-tetra- 3.99, -tri- 86.7, -di- 4.77, and -mono-methylglucoside 2.27 per cent. The conclusion is drawn that methylation is still incomplete but may involve structural changes. C.

**Diazo-Coupling Reaction: Mechanism.** H. H. Hodgson and E. Marsden. *J. Soc. Dyers & Col.*, 1944, 60, 120-124. The general mechanism of diazo-coupling put forward in a previous paper is shown to interpret (1) the coupling of phenols and naphthols, including the special cases of salicylic acid, 4-nitro-2-naphthol, resorcinol, and 1:5-dihydroxynaphthalene; (2) mobility of the azo-hydrazone equilibrium as altered by solvents, e.g. pyridine and nitrobenzene; (3) the coupling of amino compounds, including aniline and the transformation of diazoaminobenzene into aminoazobenzene; (4) the decoupling of H-acid and the exclusive monocoupling of  $\gamma$ -acid and J-acid; (5) the effect of pyridine on the coupling reaction; (6) the diazo-exchange reaction; and (7) the coupling of phenol ethers. A re-interpretation of ideas held 20 years ago, e.g. the oxonium and ammonium theories of coupling, is given on the basis of modern electronic and resonance theory. C.

**Fat Antioxidants: Application.** C. H. Lea. *J. Soc. Chem. Ind.*, 1944, 63, 107-112. Of a number of antioxidants tested in butter fat at 100° and 37° C. pyrogallol, quinol, 1:5-dihydroxynaphthalene, pyrogallol-acetone condensation product, gallic acid and its esters, pyrocatechol, and hæmatoxylin proved most powerful. Proline, protocatechuic acid, tannic acid, guaiacum resin, a concentrate of natural mixed tocopherols, 6-hydroxy-2:2:5:7:8-pentamethyl-chroman, and several other substances showed definite, but weaker activity. There was usually fairly good agreement between the relative potencies of inhibitors as observed at the two temperatures, though the degree of protection afforded by a given concentration of a particular substance appeared to be greater at 37° than at 100°. The lower esters of gallic acid proved most satisfactory in affording marked protection against oxidation without causing discoloration or imparting foreign flavour. In butter fat exposed to air at 37°, 0.005 per cent. of ethyl gallate considerably retarded the development of tallowness and loss of carotene. In lard under similar conditions, 0.01 per cent. of ethyl gallate was very effective in delaying the onset of tallowness, whilst the same proportion of this inhibitor in refined and deodorised cottonseed, arachis, and palm oils at 25° had some effect in retarding oxidation as measured by the peroxide value and, in less degree, deterioration in flavour as indicated by a tasting panel. C.

**Melamine-Formaldehyde Condensation Products.** R. Köhler. *Kolloid Z.*, 1943, 103, 138-144 (through *Brit. Chem. Physiol. Abstr.*, 1944, B II, 112). The reactions between melamine and formaldehyde with formation of plastics are discussed. The polymerisation of the primary product may occur by formation of oxygen bridges or NH.CH.NH bridges, and both reactions may take place together. Products only slightly soluble in water dissolve almost completely in pyridine. On heating, the solubility in pyridine decreases, at first slowly and then more rapidly. The unhardened resin has molecular weight 800-1,000.

On heating for some time at  $100^{\circ}$ , the molecular weight of the fraction soluble in pyridine increases to more than 3,000. A small quantity of formaldehyde is evolved on heating to  $100\text{--}150^{\circ}$ . C.

**Fibres: Genesis.** W. Ostwald. *Kolloid Z.*, 1943, 102, 35-60 (through *Brit. Chem. Physiol. Abstr.*, 1944, A I, 84); also Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1944, C:300. The general conditions determining the formation of fibres of all types, natural and artificial, are discussed. A fibre can originate by translatory motion of a nuclear disc (solid fibre) or ring (hollow fibre), and can grow either basally or apically. It may result from any of the processes of condensation, deformation, dissolution, or partial dispersion. Five fundamental questions regarding the physico-chemical conditions necessary for fibre growth are considered in detail, viz., (1) processes providing material for the growing fibre, (2) transport mechanism making the material available at the right point, (3) energy-providing processes, (4) factors determining direction of growth, (5) formative mechanism controlling shape and size of fibres. The phenomena of growth of silver fibres on heated silver sulphide and of copper fibres on cuprous sulphide are described in detail, and theories advanced which comply with the five conditions for growth. The silver ions in heated silver sulphide are mobile and exert an ionic pressure on a particle of silver in contact with the silver sulphide. This leads to deposition of silver atoms, electronic equilibrium being maintained by volatilisation of sulphur derived from sulphur ions in the lattice. Many details of the phenomenon are in accordance with the theory. The electrochemical processes are different in copper fibre formation. C.

**Soaps: Transitions between Homogeneous and Heterogeneous Systems.** J. Stauff. *Z. Electrochemie*, 1941, 47, 820 (through *Brit. Chem. Physiol. Abstr.*, 1944, A I, 85). If the state of aggregation is determined as a function of total concentration by means of the law of mass action, it is possible to distinguish between homogeneous and heterogeneous equilibria in colloid systems. The equilibrium between colloidal aggregates and single molecules in soaps has been investigated by means of colour indicators, the change being determined spectrophotometrically. When the aliphatic chain has 8, 10 or 12 carbon atoms the equilibrium is homogeneous. C.

**Chain Molecules: Kinetics of Depolymerization Reactions.** A. Matthes. *J. prakt. Chem.*, 1943, 162, 258-278 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1944, 334). If a chain molecule of degree of polymerisation  $P$  is split into  $(n+1)$  molecules of degree of polymerization  $P_0$ ,  $P$  is given by  $P = P_0/(n+1)$ , and  $n$ , the number of breaks, is given by  $n = (P_0/P) - 1$ . The number of breaks per base molecule is given by  $n/P_0 = (1/P) - (1/P_0)$ . The expression  $S = 1/P$  is termed the "degree of degradation." The increase in degree of degradation,  $(1/P - 1/P_0)$ , is independent of the course of the depolymerization reaction, e.g., it is not affected by acceleration or slowing down of this reaction. The expression  $(1/P - 1/P_0)$  can be used for comparing degree of polymerization intervals. C.

**Macromolecular Substances: Thermal Behaviour.** K. Ueberreiter. *Kolloid Z.*, 1943, 102, 272-291 (through *Brit. Chem. Physiol. Abstr.*, 1944, A I, 56 and Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1944, 116, 116.2 and 150). The properties of a substance in any state of aggregation are determined by the freedom of motion of its molecules. In liquids the thermal energy of molecules is sufficient to overcome the potential barriers surrounding them. In crystalline solids the potential barriers are all of similar magnitude; in amorphous bodies they differ, hence the melting process is not sharp, and a place-exchange occurs below the melting point, resulting in increased orientation. The freezing point of amorphous bodies is determined experimentally as the point of intersection of specific volume-temperature curves for solid and liquid. In a macromolecular liquid the chain members are more strongly influenced by their neighbours in the same chain than by those in other chains. The relative magnitudes of inter- and intra-molecular forces determine whether chains move as a whole or whether chain units move relatively to one another. The relation of chain length to freezing point shows that large molecules must be sub-divided into small kinetic units having varying degrees of thermal agitation. The state in which the kinetic energy is distributed among chain members, but not whole

molecules is described as a liquid with fixed structure. Its range of existence is greater the greater is the chain length. Macromolecular substances are classified according to their thermal properties into (i) rubber-like polymers, with weak intramolecular forces and wide temperature range of liquid with fixed structure, (ii) thermoplastics, with smaller and higher temperature range of liquid with fixed structure, and (iii) non-softening polymers, with small or no range of liquid with fixed structure. Intramolecular movement is limited by electrostatic forces, and modification of physical properties necessitates modification of electric moments, especially of side-groups or chains, e.g. chlorination of polyvinyl chloride or replacement of chlorine by ester groups lowers the freezing point by compensation or reduction of dipole moments. Internal mobility may be increased or decreased by netting of chains, according to its effect on the dipoles. External plasticisers reduce intramolecular forces and so increase the mobility of chain members. C.

**Cellulose Nitrate Solution: Viscosity Fall on Ageing; Effect of Inorganic Salts.** J. S. Gourlay. *J. Soc. Chem. Ind.*, 1944, **63**, 123-124. Solutions of sodium and calcium chlorides were shaken in the ratio of 5 vols. of aqueous solution to 95 vols. of freshly distilled acetone and allowed to settle. The supernatant liquid was then used as the solvent to make a solution of cellulose nitrate containing 20 g. of the solute per 100 ml. of the solvent. A mixture of distilled water and acetone was made up at the same time into a 20 g. per 100 ml. solution of cellulose nitrate (the "blank"). The solids contents of the three solvents were found to be: sodium chloride in solvent 0.021 g. per 100 ml.; calcium chloride in solvent 0.039 g. per 100 ml.; blank solvent 0. The solutions were aged in the dark and viscosities determined by the falling-sphere method at 25°. The results show that the presence of the salts caused a decrease in the initial viscosity of the solution and increased the rate of decrease of viscosity on ageing. It has been observed that the viscosity of solutions of cellulose nitrate made with acetone dried over calcium chloride is lower and falls more rapidly than that of corresponding solutions made with freshly-distilled acetone. C.

**Colloidal Solutions: "Viscosation."** H. Fromm. *Kolloid Z.*, 1943, **102**, 86-90 (through *Brit. Chem. Physiol. Abstr.*, 1944, A I, 84). The term "viscosation" is used to describe the increase of viscosity with concentration. Methods of expressing concentration are examined in relation to the change in size of solute particles arising from solvation. New terms and symbols are proposed for the principal magnitudes in viscosity/concentration relationships. C.

**Linear Molecules: Determination of Molecular Weights and Dimensions.** H. Umstätter. *Kolloid Z.*, 1943, **102**, 232-245 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1944, 215 and 215.2). The tensile strength of a liquid is assumed to be equal to the sum of the tensile strengths of its structural lamellae. Since the lamellae are assumed to be bimolecular, the following expression is obtained:  $r = 2\omega/E$ , where  $r$  = linear dimension of the molecule,  $\omega$  = surface tension, and  $E$  = shearing elasticity. For a number of compounds,  $E$  has been determined from the viscosity/temperature curve, and  $r$  calculated according to the given formula. Linear dimensions of the molecules can be obtained with an accuracy of  $\pm 0.75$  Å. Most high polymers are solids, and their surface tension is not known. Melting is usually accompanied by degradation so that a determination of the surface tension is not possible. In most cases, where no degradation occurs, the viscosities of the undiluted substances are so high that a determination of the shearing elasticity on the basis of viscosity/temperature curves is impossible. It has previously been shown that the molecular weight averages of solution and solvent are proportional to the squares of the absolute critical temperatures of viscosity/temperature curves of equal slope. The accuracy of the method decreases with increasing difference between the molecular weights of solvent and solute. Satisfactory results have been obtained with lubricating oils (molecular weight 300-400) dissolved in decane fractions (molecular weight about 140). Attempts to apply the method to solutions of aluminium stearate in iso-octane (molecular weights about 900 and 104, respectively) and to higher molecular lubricating oils in benzene (molecular weights above 600 and 78, respectively) were unsuccessful. In these cases, the viscosity/temperature curves of the solution are so flat that

a realisation of equal slope is impossible. The method is not applicable to high polymers. C.

**Mucin: Structure-viscosity.** P. Zamboni. *Kolloid Z.*, 1943, 102, 246-251 (through *Brit. Chem. Physiol. Abstr.*, 1944, A I, 62). A viscometer is described which enables the time of outflow to be measured at various pressures and is especially suitable for the investigation of "fibrocolloids." Structure viscosity is especially marked in solutions of mucin, but is not observed in the presence of salts in sufficient concentration. The salt concentrations necessary are of the same order as those required for the activation of enzymes that dissolve mucin. C.

**Organic Compounds: Viscosity and Hydrogen Bond Formation.** C. E. Kendall. *Chemistry and Industry*, 1944, 211. The viscosity of a liquid will depend on molecular shape and size, and on the strength of the forces between the molecules. Co-valent compounds may be roughly divided into three groups according to the intermolecular attractions present:—(a) van der Waals forces only (these increase in strength with the size of the molecules), (b) dipole attractions plus van der Waals forces, (c) hydrogen bonds plus dipole forces plus van der Waals forces. To show the influence of these forces, a diagram showing viscosity (on a logarithmic scale) against molecular weight is given. Except for the first few members each homologous series gives a straight line. The paraffins occupy the lowest portion, whilst compounds which have strong hydrogen bonds are near the top; the intermediate positions are filled by compounds which have weak hydrogen bonds or dipole forces. A comparison of groups of compounds of similar molecular weight and configuration illustrates the effect of the forces concerned. The aliphatic acids have lower viscosities than the corresponding alcohols. This can be attributed to the fact that the alcohols form transient groups of molecules linked by hydrogen bonds, whilst the acids tend to form dimers in which the hydrogen bonds are stabilized by resonance; the viscosity of an acid is roughly the same as that of a polar compound (e.g. an ester) of double the molecular weight. The viscosities of the chlorophenols suggest that hydrogen bonding occurs—mainly intramolecular in the *o*-compound (4.20 cp.), and intermolecular in the others, *m*-, 16.70 cp., and *p*-, 23.0 cp.). C.

**Ultra-violet Fluorescence Analysis Lamps.** J. A. Radley. *J. Soc. Dyers & Col.*, 1944, 60, 114-119. Sources of ultra-violet light are discussed and various high-temperature discharge lamps suitable for use for fluorescence analysis in textile laboratories are described. Suitable filters for removing visible light are discussed. C.

**Dyes: Polarisation of Fluorescence and Anisotropy.** P. P. Feofilov. *J. Physics U.S.S.R.*, 1943, 7, 68-79 (through *Brit. Chem. Physiol. Abstr.*, 1944, A I, 77). Curves showing the dependence of polarisation of fluorescent light on the wave length of the exciting light (polarisation spectra) have been obtained for rhodamine-B, Na fluorescein, Na eosin, tryptaflavine, acridine-orange, benzoflavin, Na perylenetetracarboxylate, aesculin, and pinakryptol-yellow. These polarisation spectra are specific for each dye. For Na eosin, tryptaflavine, acridine-orange and benzoflavin, the variation of dichroism of oriented molecules with wave length is investigated, and there is a correspondence between this and the polarisation spectrum. This indicates that the angles between emitting and absorbing oscillators are not produced during the excitation, but are inherent in the molecule. The anisotropy of the molecules can be interpreted by means of an oscillator model in which the fluorescing molecule is regarded as an emitting oscillator with a number of absorbing oscillators rigidly coupled to it. C.

**Fluorescent Pigments: Determination of Concentration from Fluorescence Intensity.** P. Ellinger and M. Holden. *J. Soc. Chem. Ind.*, 1944, 63, 115-121. The various methods used in fluorimetry are briefly discussed and photo-electric methods and apparatus are described. The superiority of an electrical balancing method, at least for routine work, is demonstrated. The dependence of the fluorescence intensity on the absorption of the primary light, the depth of the fluorescent layer, and the concentration of the fluorescent substance is discussed and absorption and fluorescence curves are given for a number of

pigments in various solvents. Over a wide concentration range a linear proportionality is observed between the logarithm of the fluorescence intensity and the logarithm of the concentration when narrow containers are used. The relative merits of fluorimetry and absorptiometry are discussed.

**C. Dichromat Eyes: Colour Mixture and Chroma Discrimination; Quantitative Formulation.** G. A. Fry. *J. Optical Soc. America*, 1944, 34, 159-166. Colour mixture data for dichromats are characterized by the fact that the various spectral stimuli can be matched by mixtures of two properly chosen primaries. The following equation is given for the percentage  $P$  of blue in the mixture of red and blue primaries required to match the various spectral colours of wave length  $\lambda$ :  $P = 100 / \{ 1 + 10^{K(\lambda - \lambda_0)} \}$ . The intensities of the two primaries can be expressed in terms of either energy or brightness; changing from one to the other merely changes the value of the constant  $C$ . The constant  $K$  remains relatively constant from one dichromat to another. When the intensities of the two primaries are expressed in brightness units,  $C$  is also relatively constant. The use of the formula in determining the spectral match for a heterochromatic stimulus of known wave-length composition is described. This procedure is used for calculating the spectral match for white from the colour mixture and visibility data. The calculated values are compared with the match determined by direct comparison by a protanope and a deuteranope. The procedure is also employed in testing whether colours of different wave length composition that appear alike to trichromats also appear alike to dichromats. A short method of determining the value of  $C$  for a given dichromat is described. The transformation of chroma discrimination data for dichromats from a wave-length scale to a colour-mixture scale is studied.

C.

**Ishihara Colour Blindness Test: Criticism.** R. W. Pickford. *Nature*, 1944, 153, 656-657. The Ishihara Test (8th edition, 1939) was given to 87 subjects tested with the Rayleigh equation, including 14 red-green blind men, 4 red-green blind women, 2 green anomalous men, 13 red-green weak men, 18 red-green weak women, 9 normal men and 27 normal women. No colour blind or anomalous subject gave more than one reading unequivocally correct in 24 plates. Four protanopes were not distinguished from deuteranopes by the test, nor two deuteranopes from protanopes. Moderately colour blind were not consistently distinguished from extreme, nor anomalous from colour blind. On a level of failure of 19 or less correct in 24 plates, the Ishihara Test would have failed 9 of the 31 red-green weak subjects, but not consistently the weakest, and 9 of the 36 normals. Proportions of correct, alternative and "blank" readings gave no accurate information about degree of weakness, though the test was used in a very strict manner. The conclusion is drawn that the Ishihara Test is unsatisfactory as a scientific instrument. It also errs on the side of severity (a good fault) but in an indiscriminating way.

C.

**Omega Colour Space.** J. L. Saunderson and B. I. Milner. *J. Optical Soc. America*, 1944, 34, 167-173. A further study is made of the  $\omega$ -space proposed by Moon and Spencer. Additional Munsell data are transformed to the  $\omega$ -space in order to determine with what accuracy the Munsell colour space is described by the theory. In order to facilitate the comparison of results, a standard adaptation is chosen. The  $\omega_2$  function is altered slightly to improve the agreement with the recommended data at low values. The relation between hue angle  $\theta$  and dominant wave length is investigated. Additional Munsell data are plotted in the  $\omega_1\omega_2$  planes, and a plot in the  $\omega_1\omega_3$  plane is extended to the higher chromas. Differences between the theory and the Munsell data are discussed. The  $\omega$ -space does not appear to be a sufficiently accurate mathematical description of the Munsell colour space to deserve wholehearted acceptance by colorists in industry.

C.

**Short Wave Fundamental Colour: Experimental Determination.** G. F. Göthlin. *J. Optical Soc. America*, 1944, 34, 147-158. Arguments hitherto advanced for violet and blue, respectively, as a fundamental colour in man's colour sense are reviewed and an account is given of experimental work designed to solve this problem. By means of the author's liminospectroscope, colour-threshold analyses in spectral indigo were made with five subjects of normal colour vision. With three out of the five, throughout the whole or nearly the whole of the indigo region, when the radiant flux was increased from zero, a

colour-threshold for blue was reached at a lower flux, whilst only at a higher flux did a red component begin to be discernible and add itself to the already present blue to form the special type of violet that Newton called indigo. One of the remaining subjects observed the separation into a threshold for blue and a threshold for red for a few wave lengths only and the other observed no separation. These results appear to justify the conclusion that blue has its own receptors and is the short-wave fundamental colour, whilst violet is not a fundamental colour with special receptors. This conclusion is supported by the fact that in the purest cases of congenital tritanopia the radiations of spectral violet release a sensation of colour in which only red is perceived. C.

**Microphotography Apparatus: Application.** G. W. W. Stevens. *Photographic J.*, 1944, 84, 108-111. The choice of a suitable sensitive material for the production of microphotographs, and the construction, adjustment and operation of the apparatus are discussed. Various methods of bringing a minute image to a sharp focus at the emulsion surface are critically examined. Series of exposures forming a focusing test often reveal a sharp image situated in the lower layers of the emulsion; this phenomenon is explained by considering the properties of the aerial image and of the emulsion used. C.

**Plastic Materials: Stress-Strain-Time Problems.** G. W. Scott Blair. *J. Sci. Instruments*, 1944, 21, 80-84. The foremost problem of rheology concerns the relation between stress, strain and time in complex materials. There are two ways in which the behaviour of a complex body may be expressed in terms of the Hookean and Newtonian prototypes: the analytical approach regards the material as a physical mixture of ideal Hookean and Newtonian components whereas the integrative view considers the behaviour as intermediate, molecular conditions being regarded as too complex to justify the useful construction of idealised models. Psycho-physical experiments have shown the advantages of the latter approach in studying those industrially important rheological concepts, such as "firmness," which cannot be expressed in dimensionally simple terms. It is unjustifiable to insist on the exclusive use of either method of approach: further experimentation will probably lead to their effective synthesis. C.

**Plastics Models: Use for Stress Analysis.** *British Plastics*, 1944, 16, 199-202. Notes are given on photo-elastic methods, using plastics models, for the analysis of two-dimensional, centrifugal, and three-dimensional stresses. C.

**Paint Moulds: Effect of Zinc Oxide.** S. B. Salvin. *Ind. Eng. Chem.*, 1944, 36, 336-340. Spores of fungi of species commonly found on mildewed paints were sown on paint vehicle constituents, including raw linseed oil and refined and polymerised linseed, tung, soybean and fish oils, together with lead, manganese or cobalt driers, and incubated. Varying degrees of growth were observed, with raw linseed oil providing the most luxuriant development. The effect of nine types of zinc oxide on the growth of common fungi was investigated. The inhibition of fungal growth was found to be a direct function of the surface area of the zinc oxide, a fine-particle-size zinc oxide was particularly effective. Tests showed that although zinc oxide is able to prevent the growth of mycelium or the germination of spores, it is unable to kill the spores and to prevent their germination after removal from the medium and exposure to a more favourable environment. Therefore, zinc oxide cannot be regarded as possessing fungicidal properties; its action is fungistatic. The results of respiration studies indicate that the zinc ion affects the carbohydrate metabolism of the fungus and that this action may be basically responsible for the fungistatic effect. C.

**Propylene-glycol Vapour: Bactericidal Action.** T. T. Puck, O. H. Robertson and H. M. Lemon. *J. Exper. Med.*, 1943, 78, 387-406 (through *Bull. Hygiene*, 1944, 19, 308). Observations of the bactericidal action of propyleneglycol vapour on micro-organisms suspended in air were made in a 60-litre glass chamber and in an experimental room. A given concentration is most effective when the number of bacteria-laden droplets in the air is small, a fact supporting the hypothesis that the glycol acts by condensation on these droplets. Bactericidal action is more rapid at low than at higher temperatures; this again suggests a physical rather than a chemical reaction. High and low humidity are both unfavourable: the optimum humidity for bactericidal action is about

58 per cent. Glycol vapour acts equally well on bacteria suspended for spraying in water, broth, serum broth or saliva. Artificially desiccated bacteria are also killed, but the vapour fails to sterilize an atmosphere contaminated by blowing natural room dust into it. The rate of killing of various Gram-positive cocci at different concentrations is stated: pneumococci are the most susceptible, a concentration of 1 g. in 20 million c.c. of air being rapidly lethal to them. C.

**Silkworm Lecithin: Extraction.** T. Yosida. *Bull. Imp. Sericult. Expt. Sta., Japan*, 1941, 10, 145-146 (through *Chem. Zentr.*, 1941, ii, 1161-1162 and *Chem. Abstr.*, 1944, 38, 1800<sup>3</sup>). The best method of isolating lecithin from silkworm pupae is to extract first with benzene or ether and then treat the extract with 96 per cent. ethyl alcohol at 60°. Variations in method were tried until a pure lecithin with an N:P ratio of 1:1 was obtained. Female pupae yielded a little more lecithin than male pupae. Extracts of male pupae contained an excess of fat acids and extracts of female pupae an excess of lecithinphosphoric acid. C.

**Sodium Hydrosulphite: Determination.** N. Milner. *Textile J. Australia*, 1943, 18, 324 (through *Chem. Abstr.*, 1944, 38, 1705<sup>4</sup>). The method is based on the reaction of iodine with a solution of hydrosulphite in an excess of formaldehyde. Add 20 ml. of 40 per cent. formaldehyde to a 1-l. short-necked volumetric flask and make up with water to approximately 950 ml. Add 10 g. of hydrosulphite, dilute with water to 1 l., close the flask with a stopper and shake it vigorously for 5 min. to prevent the hydrosulphite from forming a cake at the bottom. Allow at least 15 min. for the completion of the reaction. Remove 20 ml. from the flask and add it to 100 ml. of water. Add 50 ml. of 0.1N. iodine, wait 2 min. and titrate back the excess iodine with 0.1N. sodium thiosulphate; 1 c.c. 0.1N. iodine = 0.004352 g. sodium hydrosulphite. A correction should be applied for the loss of sodium hydrosulphite due to oxidation by dissolved air and by the small amount of air in the flask below the stopper before the formaldehyde has had time to act. In practice 1 per cent. is adequate. C.

**Bacterial Cellulose: Structure.** E. Franz, E. Schiebold and C. Weygand. *Naturwissenschaften*, 1943, 31, 350 (through *Chem. Abstr.*, 1944, 37, 1876<sup>6</sup>). Cellulose is separated by *Bact. xylinum* into fibres of considerable length and about 100A. thickness. A photomicrograph of 1:17,000 indicates this clearly. C.

**Corn Starch and Modified Starches: Water Sorption.** I. Sair and W. R. Fetzer. *Ind. Eng. Chem.*, 1944, 36, 316-319. Sorption isotherms of corn starch and ten of its commercial modifications are presented and discussed. Modification up to a 60-fluidity thin-boiling starch results in apparently little change in sorption behaviour. Dextrinization, with or without acid catalyst, results in products with different sorption characteristics. There is little correlation between the viscosity of the modified products and their hygroscopicity. When the moisture contents are compared with that of corn starch at the same humidity the modifications fall roughly into three groups with respect to sorption behaviour: (1) products in which the ratio of water retained is independent of the humidity, e.g. British gum and chlorine-oxidised starch; (2) products in which the ratio varies with the humidity, e.g. 90-fluidity starch, white corn dextrin, canary dextrin, and hypochlorite-oxidised starch; and (3) products in which the ratio continually decreases with decreasing humidity, e.g. the gelatinised corn starch, Amijel. Curves are also given showing the extent of hysteresis in corn starch and some of its modifications. The degree of hysteresis does not appear to be proportional to the sorptive capacity except at high humidities. Observations of the effect of severe desiccation in vacuo on the sorptive behaviour of the products are briefly discussed. C.

**Solutions and Suspensions: Flocculation.** E. Mardles. *Nature*, 1944, 153, 746-747. Flocculation in suspensions of finely divided solids in liquids can be readily demonstrated and is mainly the cause of anomalous viscosity behaviour and thixotropy. Solute particles, whether of sodium chloride, mercuric bromide, soaps or shellac, appear also to be aggregated in some circumstances, and this is demonstrated by comparing the properties of the solutions with those of the suspensions. In suspensions flocculation is associated with a large

sediment volume and a relatively high rate of sedimentation. Graphs are given showing, for solutions and suspensions in ethyl alcohol-water mixtures, the deviation below the mean solubility value of several crystalloids and the deviation above the mean value of sediment volumes of several finely divided pigments. The shapes of the curves are similar, there being a maximum deviation in the neighbourhood of the composition two molecules water, one molecule alcohol. The specific viscosity of solutions of mercuric salts, aluminium chloride, sodium chloride, etc., and of suspensions of zinc oxide, titanium oxide, etc., in alcohol increases with addition of water following the increased viscosity of the medium. The explanation of this behaviour that the higher specific viscosities are due to the longer times of orientation of asymmetric particles in the more viscous liquids can be amplified by assuming the presence of flocks which tend to orientate and break up in the stream of flow. With colloidal solutions of cellulose derivatives, proteins, resins and other large molecule substances in mixed liquids, above a certain concentration the optimum solvent mixture usually yields solutions of minimum viscosity, which are less affected by temperature than those in other mixtures. With the optimum solvent mixture there is the nearest approach to a solution of single molecules. Palit has suggested that the explanation of the viscosity behaviour in mixed liquids has its roots in the gelation (flocculation) capacity of the system, and such solutions above the minimum gelation concentration may be regarded in a limited sense as incipient gels. In other words, in solutions of some concentration and in the poorer solvents, e.g. two molecules water—one molecule alcohol mixture, the solute molecules are to a greater or less extent in an aggregated state. C.

**Radiant Energy: Specification and Measurement.** Committee on Colorimetry, Optical Society of America. *J. Optical Soc. America*, 1944, 34, 183-218. A survey is made of definitions of the quantities and units employed for the specification of radiant energy and the capacities of materials and objects to radiate, modify, and detect radiant energy, and methods and apparatus for the measurement of such quantities. The following are the main headings: radiant flux and radiant intensity; spectral composition and spectral distribution; spatial variants for the specification of radiant energy; reflectance, transmittance, absorptance; importance of spatial conditions of measuring reflectance and transmittance; reflection: Lambert's law and Fresnel's formula; transmission and absorption: Bouguer's and Beer's laws; transmittance, opacity and density; internal transmittance, transmissivity, absorptivity; transmittance and reflectance of turbid media; integration of spectral transmittance, reflectance and absorptance; polarization; polarizing prisms; optical activity and rotatory dispersion; interference of polarized light; elimination of polarization errors in photometry; thermal radiation; spectral emittances of complete radiators; emissivity; radiation and brightness temperatures; colour temperature; radiometry; selective detectors; the modulation of radiant energy; selective filters; photometry; dispersing systems; visual spectrophotometers; photo-electric spectrophotometers; spectrophotometry. C.

**Colour Combinations: Aesthetic Measure.** P. Moon and Domina E. Spencer. *J. Optical Soc. America*, 1944, 34, 234-242. According to Birkhoff, æsthetic measure is equal to the number of elements of order divided by the complexity. The application of this general formula to colour requires the determination of the weights to be given to elements of order and complexity. Such factors as identity, similarity and contrast of hue, value and chroma, ambiguity, and area balance have been evaluated by means of experiments with colour chips. The results of the experiments are summarised, and instructions are given for the calculation of the æsthetic measure of any colour combination. A table of calculated æsthetic measures for various classes of harmonies is given. The ratings lead to the following conclusions: Correctly related grays give essentially as high an æsthetic measure as chromatic colours. A harmony with constant hue tends to be very pleasing. Constant value, on the other hand, tends to give low æsthetic measures. Simple designs with constant hue and constant chroma are often more satisfactory than very complicated combinations with many hues. C.

**Solutions: Light Scattering.** P. Debye. *J. Applied Physics*, 1944, 15, 338-342. The scattering of light in an ideal gas of low density, in liquids, and in solutions is studied and equations are given for the turbidity, which is defined as the fractional decrease of the primary intensity over unit distance. By a combination of the turbidity, with the difference in refraction of solution and solvent, the molecular weight of the substance in solution can be evaluated, without introducing any kind of empirical constants. Scattering by particles of a size comparable with or larger than the wave length of the light is briefly discussed. Information about particle size can be obtained from observations of the dissymmetry in angular distribution of scattered intensity and the dependence of the intensity of scattering in a definite direction on the colour of the primary light. C.

**Polymerised Methyl Methacrylate: Elasto-viscous and Stress-optical Properties.** H. A. Robinson, Ruth Ruggy and Elizabeth Slantz. *J. Applied Physics*, 1944, 15, 343-351. The elasto-viscous and stress-optical properties of commercial methyl methacrylate polymer have been measured at various temperatures. Between 66°C. and 107°C. Young's modulus drops from approximately 400,000 lb. per sq. in. to roughly 200 lb. per sq. in. and the material behaves like rubber. At 93°C. the viscosity is approximately  $10^{12}$  poise. This drops to  $10^9$  at 177°C. Although the curve is not strictly linear with  $1/T$ , an activation energy of 30,000 cal./mole can be deduced for this change. Below 93°C. three rate constants are necessary to describe the delayed elastic process, but two suffice between 93°C. and 135°C. At 149°C. one such constant is enough and above this an instantaneous elastic and a viscous flow are sufficient. The change in rate constants with temperature gives rise to elastic activation energies of 9,000 to 11,000 cal./mol. Polymerised methyl methacrylate is optically negative, but has a stress optical sensitivity about that of glass. The stress optical coefficient varies markedly with temperature, showing a sharp maximum at 93.3°C. The stress-optical coefficient is directly proportional to the average relaxation constant. X-Ray diffraction patterns of methyl methacrylate fibres show four sizes corresponding to spacings of 2.19, 3.07, 6.7 and 14.7 Å. Some slight evidences of crystallinity are shown by diffraction patterns in fibres stretched at 93°C. Fibres stretched at 149°C. show a lesser amount of order in agreement with the birefringence studies. The second-order transition point occurs at 71.1°C. C.

**Rubber: Elasticity; Theory.** H. M. James and E. Guth. *J. Applied Physics*, 1944, 15, 294-303. Natural rubber is the prototype of an important class of materials, all consisting, at least in part, of long flexible molecules. Some of the properties of bulk rubber may be understood by a consideration of the very similar properties of single flexible molecules. In vulcanized materials, in which plasticity is suppressed, intermolecular bonds link the molecules into a coherent network, very irregular in detail but isotropic and homogeneous on the average. In lightly vulcanized materials these bonds are relatively few, and bring relatively small portions of adjacent molecules into fixed relations to each other. For the most part the interaction of neighbouring molecules in the material is that characteristic of liquids. It is the presence of the intermolecular bonds, which link the molecules into a network and thus control its form, that differentiates rubber-like materials from liquids and it is the small number of these bonds, and their weak control of the form of material through the entropy rather than the internal energy, which differentiates rubber-like materials from ordinary solids. On the basis of this picture of the structure of rubber there is derived a form for the stress/strain curves at moderate extensions which is in good agreement with experiment. C.

**Rubber-like Materials: Hysteretic and Elastic Properties.** J. H. Dillon, I. B. Prettyman and G. L. Hall. *J. Applied Physics*, 1944, 15, 309-323. The nature of hysteresis in products such as pneumatic tyres, solid tyres, and transmission belts is analysed and the requirements of a laboratory test for evaluating the relative hysteretic characteristics of natural and synthetic rubber stocks are developed. The significance of various definitions of the "hysteresis defect" on rubber-like materials is discussed. A forced resonance vibrator in which rubber samples are deformed in shear at frequencies of 20 to 300 cycles/sec., shear strains of 0.05 to 0.35, and temperatures of -20 to +120°C. is

described. Experimental results obtained with natural rubber and GR—S gum and tread stocks are presented. The hysteresis index  $\omega\eta$  is nearly independent of dynamic shear strain whilst the dynamic modulus  $G$  depends upon the ratio of height to diameter of cylindrical samples. These results are at variance with those obtained by previous investigators who, employing compressive vibrations, have reported marked dependence of both modulus and friction upon dynamic strain and the "shape factor" of tread type stocks. In agreement with previously reported work,  $G$  is found to be independent of frequency and  $\omega\eta$  only slightly dependent upon frequency, for tread type stocks. C.

**Fats, Oils and Soaps: Review of Literature for 1943.** M. M. Piskur. *Oil and Soap*, 1944, 21, 65-72, 108-123. The literature is reviewed under the headings: General; technical treatment; products (except detergents); deterioration; biochemical; characteristics and composition; detergents. W.

**Mineral and Trace Element Metabolism in Animals and its Relation to Deficiency Diseases.** S. J. Watson. *Chem. & Ind.*, 1944, No. 15, 138-141. Knowledge of the physiological action of mineral elements is scanty. Trace elements appear to act as catalysts and to be bound up with the enzyme systems of the cell. Ruminants suffer much more from their deficiency than do the simple stomached animals. Work on "pine" diseases in sheep in various parts of the world is surveyed. These are curable by the administration of copper or cobalt or both, but so little is known of the interaction and antagonism of the different trace elements that care must be exercised in their use. W.

#### PATENTS

**Chlorine Dioxide: Production.** Mathieson Alkali Works. B.P.561,170 of 28/10/1942:8/5/1944 (Conv. 26/9/1941). Chlorine dioxide substantially free from chlorine is produced by treating a metal chlorate with sulphuric acid in the presence of a persulphate, preferably in proportion approximately equivalent to that of the chlorate, at a temperature not substantially exceeding 50° C. C.

**Starch Syrups: Preparation.** A. E. A. Beaver and Corn Products Co. Ltd. B.P.561,706 of 11/11/1942:1/6/1944. For the manufacture of syrups from starch, a starch suspension is first subjected to the action of a bacterial enzyme, e.g. an enzyme derived from *B. subtilis*, *B. vulgatus* or *B. mycoides*, which is capable of reacting with starch in water suspensions and destroying the gelatinising properties. The starch is then saccharified by malt or other vegetable diastatic inversion. The process can be applied usefully to starch suspensions above 7° Bé., and is particularly advantageous with relatively heavy suspensions. The proportion of malt diastase required in this process is considerably less than is customary in diastase inversion and may be of the order of 5 per cent. or more. C.

**Carob Gum: Improvement of Gelling Properties.** K. Brauer (Tel-Aviv, Palestine). B.P.561,762 of 18/12/1942:2/6/1944 (Conv. 20/12/1941). Carob gum is subjected to treatment with hot solutions or suspensions of bases or alkaline reacting salts, e.g. sodium hydroxide, in ethyl or methyl alcohol or a like solvent. Salts of calcium or iron may be used as catalysts. After washing and drying, there is obtained a powder which forms a jelly when mixed in the usual manner with water, the jelly being similar to those prepared with agar-agar or pectin. C.

### 10—ECONOMICS

**American Wool Council: Operations in 1943.** F. E. Ackerman. *Natl. Wool Grower*, 1944, 34, No. 2, 17-18. W.

**American Viscose Yarns: List Prices.** *Rayon Organon*, 1944, 15, 34-36. List prices at various dates between September, 1919, and September, 1941, are tabulated for American yarns for weaving, of 50, 75, 100, 125, 150, 200, 300 and higher deniers. C.

**Cotton Lint: Consumption in the United States, 1913-1943.** *Rayon Organon*, 1944, 15, 28. American monthly lint cotton consumption figures are given for the period 1913-1943. C.

**Cotton, Wool, Silk and Rayon: Spot Prices, 1914-1941.** *Rayon Organon*, 1944, 15, 24-25. Monthly average spot prices of raw cotton, scoured raw wool, raw silk, and rayon filament yarn are tabulated for the period 1914-1941. C.

**Raw Silk: Consumption in the United States, 1920-1941.** *Rayon Organon*, 1944, 15, 26. Monthly deliveries of raw silk to United States mills are tabulated for the period 1920-1941, and annual consumption and re-export figures are given. C.

**Rayon: Consumption and Production in Canada.** *Rayon Organon*, 1944, 15, 54-55. A table is given showing Canadian production of viscose and acetate yarns, and filament yarn and staple fibre imports and consumption in the years 1925 to 1943. Total rayon filament yarn and staple fibre consumption in Canada in 1943 amounted to 27,073,395 lb., 0.8 per cent. above the 1942 consumption and 75 per cent. above consumption in 1938. Total domestic viscose and acetate yarn production declined from 18,450,000 lb. in 1942 to 16,550,000 lb. in 1943, but imports increased from 3,530,634 lb. to 4,823,419 lb. Courtaulds' (Canada) Ltd. production of viscose yarn declined from 11,250,000 lb. in 1942 to 9,350,000 lb. in 1943. The estimated production of Canadian Celanese Ltd. (7,200,000 lb. of acetate yarn) remained unchanged from the previous year. Approximately 13 per cent., or 2,600,000 lb., of the total yarn supply, excepting imports of acetate yarn from Britain, was delivered to the full-fashioned hosiery industry. Staple fibre imports during 1943 reached 5,699,976 lb., compared with 4,881,989 lb. in 1942, an increase of 17 per cent. Approximately 95 per cent. of Canada's staple fibre imports were from Britain. C.

**Rayon: Production and Consumption in the United States.** *Rayon Organon*, 1944, 15, 15a-19. Tables and graphs are given showing annual productions of rayon filament yarn and staple fibre during the period 1911-1943, and the distribution of domestic rayon consumption by trades and of yarn production by denier in recent years. Total rayon production (yarn and staple fibre) in the United States in 1943 reached a record figure of 663,100,000 lb., an increase of 5 per cent. over that of the previous year. Compared with the 1942 figures, viscose + cuprammonium filament output showed an increase of 9 per cent., acetate a decline of 4 per cent., and rayon staple an increase of 6 per cent. in 1943. Viscose and cuprammonium yarn consumption increased in tyre production and broad and narrow fabric weaving sections. Notable increases occurred in acetate filament consumption in the hosiery trade. The average denier of the viscose and cuprammonium yarn production in 1943 was 157 denier, compared with 140 denier in 1942 and 139 denier in 1941. C.

**Textile Fibres: Consumption in United States.** *Rayon Organon*, 1944, 15, 20-21, 44-47. (1) Monthly consumption figures and consumption or activity indices are given for cotton, silk, wool and rayon for the period 1925-1943. (2) Tables and graphs are given showing annual consumptions of cotton, wool, rayon and silk in the United States in the period 1920-1943. In 1943, total fibre consumption reached 6,520,400,000 lb., a decline of 4.8 per cent. from the previous record year. Consumption of cotton, at 5,236,400,000 lb., showed a drop of 6.7 per cent., scoured wool (627,900,000 lb.), an increase of 2.3 per cent., and rayon (656,100,000 lb.), an increase of 5.7 per cent., compared with the corresponding figures for 1942. Very small amounts of silk were imported from Italy and China. C.

**United States Rayon Filament Yarn Exports.** *Rayon Organon*, 1944, 15, 25. Annual exports of rayon filament yarn for 1925-1941, monthly exports for 1929-1941, and annual exports by countries of destination for 1925-1941 are tabulated. C.

**United States Rayon Imports.** *Rayon Organon*, 1944, 15, 22-23. Tables are given showing annual imports of rayon filament yarn, staple fibre and waste (in pounds and dollars) for 1922-1941, monthly imports of rayon filament yarn, staple fibre and waste for 1929-1941, annual imports for consumption of rayon staple fibre by countries of origin 1928-1941, and annual general imports and imports for consumption of rayon filament yarn and rayon waste by countries of origin, 1922-1941. C.

**Plastics and their Raw Materials: Development.** H. Levinstein. *Chemistry and Industry*, 1944 226-230. Available supplies of calcium carbide in Britain, coal, petroleum, and fermentation products as raw materials for the plastics industry, hydrogen, methane, and ethylene in coal or coke oven gas as raw materials, and problems of price and supply are reviewed. Developments in

plastics, rayon and synthetic rubber industries in the United States, Germany and Japan are briefly considered. The correlation of the plastics industry with other industries is discussed, and requirements for the rapid development of the British plastics industry are outlined. A bibliography, divided into sections relating to coal, methane, and petroleum, respectively, as sources of raw materials for chemical industry, is given. C.

**Rationed Clothing, Footwear and Textiles: Retail Outlets.** *Bd. Trade J.*, 1944, 150, 201-205. In May, 1942, traders handling goods controlled by the Consumer Rationing Order (clothing, footwear, hand-knitting yarn and dress materials) were required to open a coupon account at a bank. From the forms of application submitted by retailers, statistics have been compiled showing the numbers of such shops and analyses by size and type. By the middle of 1942, 86,150 retail shops had opened accounts; of these about 81,000 were primarily engaged in selling rationed clothing and textiles, the remaining 5,000 dealing in clothing only as a side-line. It is estimated that possibly 10 per cent. of shops wholly or mainly selling rationed goods may not have opened accounts, these being mainly very small shops. Of the 86,150 shops, 9 per cent. have total sales amounting to more than £12,000 per annum, 43 per cent. have turnovers of £2,500-£12,000, and 48 per cent. under £2,500 per annum. The distribution according to types is 10 per cent. multiple shops, 3 per cent. co-operative stores, and 87 per cent. independent shops. The multiple and co-operative shops fall almost entirely in the two upper turnover classes. Classifications according to the lines of goods sold and according to general descriptions, and the distribution of shops by the lines they handle in each of the Civil Defence regions are shown, together with estimates of the population per shop in the various regions. For the United Kingdom as a whole the average number of persons to a shop in 1942 was 521. The number of persons per shop was generally higher in the southern part of the country than in the north. C.

**Textile Wholesale Prices, May, 1944.** *Bd. Trade J.*, 1944, 150, 221. The wholesale price index numbers for May are Cotton 159·3, Wool 183·9, Other textiles 134·3 (1930=100). C.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY AND EDUCATION

**Tootal Broadhurst Lee Co. Mill School: Organisation.** J. E. Townsend. "*Times*" *Trade & Engineering*, 1944, 55, May, p. 23 and 47. For many years it has been the policy of the Tootal Broadhurst Lee Co. to assist young people joining its business to continue their academic education after leaving school and at its Bolton Mills it has its own part-time day continuation school, which has continued without interruption since 1918. The curriculum is entirely non-vocational, and for boys embraces mathematics, sciences, English composition, history, geography, literature, drawing, woodwork, and physical exercises. Girls exclude woodwork, but instead take hygiene, housewifery, household accounts, needlework, and cookery. The school is provided by the company, is fully staffed by qualified teachers, and is under the inspection of the Board of Education. All employees at the firm's Bolton Mills under the age of 16 must attend this school two half-days a week up to the age of 18 years. All instruction, school materials and school costumes, full dental and minor medical treatment are provided free. Wages are made up for the time spent in the school. It is generally acknowledged that the improvement in the girls and boys, mentally, physically and socially, has been most marked. The firm's guidance and assistance are also given for the operatives to continue their studies at local evening technical classes. In Manchester, girl operatives at the mills and works have been attending (until they attain 18 years of age) the local day continuation school. Young employees in the distributing warehouse and offices are sent either to a day continuation school or to part-time day classes at the High School of Commerce, according to the standard of education they have already reached. In addition to these non-vocational studies, a vocational training scheme has recently been introduced for the Manchester staff. The entrants are divided into three groups: Class A—the elementary school, boys and girls; Class B—secondary school, boys and girls; Class C—

university graduates. This scheme covers a period of years and provides the basis of a vocational training upon which the student can later build his specialized study. It is possible for a bright child from an elementary school to pass forward into the later stages of the training and onwards to a university degree. Over 20 years ago the firm established laboratories at its headquarters and mills. In its Manchester laboratories alone there is a normal staff of 40 fully qualified scientists, whose functions include pure research and the maintenance and improvement of the quality of the firm's production. Whilst the firm uses the services of designers from all over the world, a large proportion of the patterns and designs for its fabrics are produced in its own art departments in Manchester and London. In addition it has a special staff for the designing of model gowns. C.

**Chilean Textile Factories: Health Hazards.** A. Forero and J. Thomas. *Rev. Chilena de Hig. e Med. Preventiva*, 1943, 5, 359-386 (through *Bull. Hygiene*, 1944, 19, 287-288). A report is given of a study of 282 factories in Chile, employing 8,770 operatives and processing chiefly cotton, jute, hemp, vegetable silk, wool, goat, llama and rabbit hairs, and rayons. The various processes are briefly reviewed and the hazards from the dust and fibres, mainly respiratory, bronchitis, allergic symptoms, byssinosis, and conjunctivitis, are discussed. Hemp fibre causes a disease which is similar to silicosis. Skin conditions arise from the dyes and from chlorine, alkalis, acids and benzole. Risks are greatest in carding and dyeing rooms. Illustrations (in the original paper) show how the masses of dust collect, the masks used, the structure of the constituent filters and the quantity of dust thereby removed from the inspired air. C.

**Nitrous Fumes in the Atmosphere: Permissible Limits.** C. P. McCord. *Industrial Standardization*, 1944, 15, 41. Permitted concentrations of nitrous fumes range from 1 part per million (Soviet Russia) to 1400 p.p.m. (a non-official German standard), but 39 p.p.m. is the commonest figure. The American Standards Association, on the recommendation of the American Association of Industrial Physicians and Surgeons have now fixed 25 p.p.m. as the limit. The toxic effects of nitrous fumes are briefly described. C.

**Toxic Anæmia: Causes and Occurrence.** Ethel Browning. *J. Ind. Hyg. & Toxicol.*, 1943, 25, 124-131 (through *Bull. Hygiene*, 1944, 19, 283). Toxic anæmia, which is notifiable under the British Factories Act, may be regarded as a dyshaematopoietic anæmia. Industrial toxic agents act on the bone marrow to produce a wide variation of disturbance according to the composition of the agent, the severity of exposure, and the susceptibility of the victim. Benzole with heavy exposure causes severe leucopenia with a total white cell count as low as 104 per cu. mm.; with milder exposure leucopenia is not a predominant feature, but relative lymphocytosis occurs. Xylol produces an effect similar to, though less severe than, that of benzole. Carbon tetrachloride is not primarily dyshaematopoietic, but it may cause secondary anæmia; one case, however, is quoted of fatal jaundice where the bone marrow was definitely hyperplastic. Solvent naphtha contains not more than 2 per cent. of benzole and toluole; it may originate slight secondary anæmia, but no effects comparable with those due to benzole or toluole. Trichlorethylene is not usually considered a blood poison, but two cases, one of fatal aplastic anæmia, the other of severe hypoplastic anæmia, have been ascribed to it. Mixed solvents and thinners (mixtures of hydrocarbons, chloro compounds and ketones) used in spraying with cellulose are not so insidiously dangerous as the benzole group; they cause malaise before doing serious harm. Two cases, one fatal, of myeloid leukaemia are quoted, due to using, for cleansing purposes, thinners containing some benzol. Radio-active substances for luminizing dials are used with strict precautionary measures and so far, no toxic results giving cause for alarm have occurred in Britain. Some relative lymphocytosis has been observed, due, possibly, to a hyperstimulative influence on the haematopoietic system. C.

**Post-war Textile Research.** P. Larose. *Canadian Text. J.*, 1944, 61, No. 9, 47-48. The need is stressed for more intensive post-war textile research, and the range of problems requiring investigation briefly indicated. W.

# THE JOURNAL OF THE TEXTILE INSTITUTE

## ABSTRACTS

### 1—FIBRES AND THEIR PRODUCTION

#### (B)—ANIMAL

**Bacteria Responsible for the Loosening of Wool on Sheepskins.** M. E. Maxwell and F. G. Lennox. *Nature*, 1944, 154, 118-119. Two new experimental methods for investigating the sweating process of fellmongering are: (1) following the course of wool loosening by measuring the depilation load, and (2) sterilizing sheepskin and removing the sterilizing agent to permit investigation of the wool-loosening activity of pure cultures of bacteria. Sterilizing in this way and measuring the depilation load during incubation at 25° C. after inoculation with pure cultures of bacteria, showed, that of the 75 species and strains of bacteria occurring on sheepskins, only 4 reduced the depilation load to zero within 41 hr. *Proteus vulgaris* is probably the principal sweating bacterium. W.

**"Stickers."** *Sheep Breeder*, 1943, 63, No. 11, 5-6 (through *Biol. Abs.*, 1944, 18, F, 6693). Stickers, the spear-pointed seeds of a number of weeds, are of considerable economic importance to the sheep industry. Regions of the body most affected and the lesions caused are described. Suggestions are given which if followed should reduce the losses to the livestock and meat industry. W.

**Nutritional Anæmia of Sheep on Granite Pastures of New Zealand (N.S.W.): Experiments with Mineral Licks.** W. L. Hindmarsh. *Agric. Gazette, New South Wales*, 1944, 55, 123-126. The administration of various minerals known to be lacking in the soil and pasture did not appreciably affect the health, condition and wool production of comparable groups of sheep. Comparison with similar sheep grazed on improved pasture suggests that the sheep do not lack any specific substance or mineral in the winter diet, but merely require good food. W.

**Increasing Clean Fleece Weights.** R. H. Burns. *Natl. Wool Grower*, 1944, 34, No. 1, 18-19. A study of the amount of clean wool per sheep in Wyoming flocks since 1940. Wyoming ranks first in the U.S.A. for greasy fleece weight per sheep (9.8 lb. in 1943). The methods suggested by the Wool Department at Wyoming University for increasing the clean yield of Wyoming flocks are listed. W.

**Wool Clips: Preparation.** A. Johnston. *Natl. Wool Grower*, 1944, 34, No. 3, 25. Wool clips should be prepared in a manner acceptable to the wool trade, and the necessary recommendations are made. This is especially important in view of the core-sampling tests for determination of yield to be undertaken by the Wool Division of the Livestock and Meats Branch, Office of Distribution, War Food Administration, U.S.A. W.

**Sheep Shearing in India.** P. N. Nanda and G. Singh. *Indian Fmg.*, 1943, 4, 188-200. Details are given of the basis of valuation of wool for purchase, 25 per cent. of the marks being allotted to clean yield which depends solely on efficient shearing. Unless climatic conditions are unfavourable, it is advantageous to shear twice a year. Times for shearing, preparation for shearing and the operation itself are discussed. W.

**Skinfolds in Sheep.** M. A. Madsen, A. C. Esplin and R. W. Phillips. *Utah State Agric. College, Agric. Exper. Sta., Bull.* 307, 1943. The literature is reviewed on the relation of skinfolds to wool production, their inheritance, and the effect of nutrition on their development. From a study of the flock of Rambouillet ewes at the Utah State Agricultural College, information is given on the inheritance of skinfolds and the value of early estimates of their amount

for predicting this character in yearlings, the applications of these findings to sheep breeding being discussed. W.

(C)—VEGETABLE

**Dholleras Cotton: Improvement.** *Indian Farming*, 1943, 4, 468-469. Wagad cotton forms the essential constituent of commercial Dholleras cotton. With a ginning outturn of 39 per cent. and a staple length of  $\frac{3}{4}$  in., Wagad is capable of spinning 13s highest standard warp counts and is both hardy and resistant to adverse climatic conditions. The Lalio or Broach *desi* and Goghari mixture which forms a second constituent of Dholleras cotton is of the same general character as Wagad. A third constituent is Mathio, a hardy early variety of *arboreum* cotton which gives a coarse type of lint of low spinning value. Attempts to improve Wagad cotton have resulted in the selection of a strain known as Wagad 8 which is superior to local Wagad. Schemes for the improvement of Wagad and the replacement of Mathio are now in operation. A few selections from local Wagad have been obtained which are good in respect of staple length and spinning performance. A segregate 4-1 from the back-cross (Wagad 8  $\times$  1027 ALF)  $\times$  Wagad 8 is capable of spinning up to 16s warp counts and is considered to be a profitable type for general cultivation. The segregate 7-1, isolated from the cross Wagad  $\times$  1027 ALF, has done well in the Lalio tract around Mehsana. Mathio is being replaced by the Bengals strain C520 which is superior in yield, ginning percentage and quality. C.

**Improved Indian Cottons: Cultivation in United Provinces, India.** B. L. Sethi and M. A. A. Ansari. *Indian Farming*, 1943, 4, 461-462. Details are given of the characteristics of the improved types of cotton, C520 and Perso-American, now being grown in the United Provinces. C520, a single-line selection from indigenous material, is an early hardy variety with a ginning percentage of 35.5 and a staple length of 0.76 in.; it is capable of spinning up to 13s warp counts. Perso-American is a single-line selection from exotic material (*G. hirsutum*) imported from Iran. It is a high-yielding and early variety with a ginning percentage of 32 and a staple length of 0.88 in. and is capable of spinning up to 32s warp counts. The results of tests demonstrating the superiority of these varieties over local *desi* in yield and quality are given. During the past eight years the area under C520 has extended from 17,419 to 33,231 acres. The area under Perso-American has increased from almost nil to 12,000 acres in the past four years. Seed supply and marketing schemes are described. C.

**Bollworm, Boll Weevil, Cotton Aphid and Flea Hopper: Control.** K. P. Ewing and R. W. Moreland. *J. Econ. Entom.*, 1942, 35, 626-629 (through *Brit. Chem. Physiol. Abstr.*, 1944, B III, 89). Basic copper arsenate-sulphur or calcium oxide dusts gave higher cotton yields than lead or calcium arsenate or cryolite in control of the bollworm and boll weevil, and higher yields than sulphur or sulphur-arsenical mixtures in flea hopper control. Increase in aphids after dusting with basic calcium arsenate-sulphur was more than 50 per cent. of that following calcium arsenate or zinc-softened calcium arsenate dusts. Addition of rotenone (0.5 per cent.) to calcium arsenate dust left 3.6 times as many aphids on cotton as did addition of 1 per cent. of nicotine. Calcium arsenate-zinc sulphate was not a satisfactory aphicide. C.

**Cotton Aphid and Boll Weevil: Control.** I. J. Becnel and E. H. Floyd. *J. Econ. Entom.*, 1942, 35, 623-626 (through *Brit. Chem. Physiol. Abstr.*, 1944, B III, 89). The effects of calcium arsenate, with and without sulphur (10 per cent.) and rotenone (0.5 per cent.), nicotine (1 per cent.), and sulphur (10 per cent.) plus pyrethrins (0.2 per cent.) on the cotton aphid and boll weevil, and on yield of seed cotton, are discussed. C.

**Hemipterous Cotton Insects: Control.** J. R. Eyer and J. T. Medler. *J. Econ. Entom.*, 1942, 35, 630-634 (through *Brit. Chem. Physiol. Abstr.*, 1944, B III, 89). Preventive applications of Paris green-sulphur dusts for hemiptera control gave an increase in yield of 246 lb. of seed cotton per acre. Smaller gains were obtained by dusting with calcium arsenate-sulphur and sulphur-resin mixtures. The arsenical-sulphur combinations also gave high mortality of *Chlorochroa sayi*, *Lygus hesperus*, and *Adelphocoris superbus* in large field cages. C.

**Cotton Plant Puller: Application.** C. V. Sane. *Indian Farming*, 1943, 4, 602-603. Serious damage to the cotton crop in Gujarat is caused by the spotted bollworm. The usual method of dealing with the old cotton stalks was to hack

them with a spade which left all the underground root system intact. In the soils of Gujarat these soon produced secondary growth giving to the bollworm shelter and food and an opportunity to continue the brood. The plant puller takes away the main root system along with the stalk, so that secondary shoots do not come up. In addition to depriving the bollworm of food and shelter in this way, the use of the plant puller makes easier the working of the land after rain by other cultural implements. Certain objections that have been raised to the use of the puller are discussed and answered. The encouragement of its general adoption by propaganda and legislation is discussed and progress in the Navsari and Baroda districts is described. C.

**American Cotton: Production, 1943-44.** U.S. Dept. Agric. Crop Reporting Board. *Textile Weekly*, 1944, 34, 98, 100. Statistics of acreage, yield per acre and ginnings are tabulated for the different cotton-growing States, 1942 and 1943. The total area harvested in the 1943-44 season was 21,652,000 acres, the average yield 253.5 lb. per acre, and the total of ginned cotton 11,427,000 bales (500 lb.). This includes some 300 bales of Sea Island cotton and 60,900 bales of American-Egyptian. Another table gives the values of cotton lint and cottonseed for the different States. C.

(D)—ARTIFICIAL

**Tantalum Spinneret Cups: Production.** C. C. Downie. *Silk & Rayon*, 1944, 18, 661-2. A general account is given of the properties of tantalum and its fabrication into rayon spinneret cups. C.

PATENTS

**Modified Regenerated Cellulose Fibres and Films: Production.** E. I. Du Pont de Nemours & Co. B.P.562,184 of 27/11/1942:21/6/1944 (Conv. 27/11/1941). Cellulosic fibres, yarns, films and other structures which are capable of being dyed with wool dyes, particularly "neutral" dyeing wool dyes, are produced by spinning an aqueous alkaline solution of cellulose, e.g. viscose, into which has been incorporated a water-soluble polymer having an intrinsic viscosity of at least 0.5 and comprising the reaction product of a substantially equimolecular mixture of a dibasic carboxylic acid and a diamine containing at least two oxygen atoms in the chain separating the amine groups. The best results are obtained by incorporating into the viscose about 5-20 per cent. of the polymer based on the weight of the cellulose in the viscose. Dyeings made with wool dyes are practically as fast to washing as similar dyeings on wool and superior to dyeings on regenerated cellulose materials containing basifying agents of the protein type. C.

**Cotton Plant Dusting Device.** C. W. McLaughlin. U.S.P.2,336,113. The claim is for a unit duster that can be readily mounted on an agricultural vehicle for feeding [insecticidal] dust to a set of nozzles connected to a conduit that extends laterally from the main part of the apparatus. A motor-driven fan is mounted in this part to force the dust to the conduit through semicircular openings that can be closed by a slide valve. C.

**Cellulose Ester: Melt Spinning.** Herculese Powder Co. U.S.P.2,336,159. Thin filaments of a cellulose lower fatty acid ester are obtained without the use of solvents or plasticizers by extruding the semi-fluid mass at 425-560° F. through an orifice, and stretching and cooling. The combined effect of time and temperature is such that the decrease in specific viscosity of the ester is less than 50 per cent. C.

**Cuprammonium Cellulose Spinning Solution: Preparation.** Industrial Rayon Corporation. U.S.P.2,336,481. A mixture of ammonia solution, copper hydroxide and cellulose in the ratio  $\text{NH}_3:\text{Cu}(\text{OH})_2$ : dry cellulose of 0.5—0.8:0.6:1 is agitated at a temperature of less than 10° C., maintained by external cooling. C.

**Fabric Spinning Apparatus.** F. W. Manning. U.S.P.2,336,743. A thermoplastic material is extruded through a spinneret in a chamber on to a retaining wall on which the filaments are deposited, while still plastic enough to adhere together, in such a manner that they interlace and form a pervious web. The apparatus is shown in a diagram. C.

**Tampon Spinning Apparatus.** F. W. Manning. U.S.P.2,336,744. Tampons with pull cords are made by sifting an absorbent material at uniform intervals

through a primary foraminous wall to form pads on an adjacent secondary foraminous wall about a central cord, removing the pads and compressing them into relatively rigid cartridges, and then spinning a web of filaments over each cartridge. The apparatus is shown in a diagram. C.

**Fabric Spinning Apparatus.** F. W. Manning. U.S.P.2,336,745. The filament from a spinneret passes through an ejector where it is disrupted by means of an elastic fluid, and the stream of fluid is made to deposit the reduced filaments upon a foraminous wall as a homogeneous web. The apparatus is shown in a diagram. C.

## 2—CONVERSION OF FIBRES INTO FINISHED YARNS

### (A)—PREPARATORY PROCESSES

**Compressed Cotton: Opening.** *Cotton (U.S.)*, 1944, 108, No. 3, 134-135. A correspondent gives particulars, with diagrams of his machinery lay-out, of methods for opening compressed cotton. *High-density bales* (32 lb. per cubic ft., 15½ cub. ft. per bale) are opened 100 at a time. The cotton is pulled off in strips and fed to a series of five hoppers. It is then carried by a lattice to a vertical opener (at 550 r.p.m.) and to a down-stroke beater (at 400 r.p.m.). The loosened cotton then travels through about 40 feet of "gyrator" to a press where it is made up again into bales of the standard size but weighing only 350-400 lb., and bound by 3 or 4 ties only. These loose bales are then treated like the ordinary "flat" or "country" bales (14 lb. per cub. ft.; 45 cub. ft. per bale) but are first stored for at least 24 hours, which is claimed to increase production at the card by about 4 lb. per hour. (The cotton used by the mill is 1⅜-in. strict middling, or better.) *Standard compressed bales* (22 lb. per cub. ft.; 22½ cub. ft. per bale) are opened 40 at a time. Four bale breakers feed the cotton *via* a conveyor belt, gyrator and three hoppers to three Aldrich beaters (1,000 r.p.m.) and vertical openers (550 r.p.m.) and thence through trunks to the scutcher hoppers. When these hoppers get full, the hoppers before the beaters stop, and when these fill up the bale breakers stop. (The standard compressed cotton used in this mill is Western, 1-in. staple, and strict low bright in grade.) C.

**Drawframe Rollers: Effect of Setting on Spinning Breakages.** H. L. Pratt. *Cotton (U.S.)*, 1944, 108, No. 4, 104-105. A report is given of counts of "ends down" each hour over a period of 8 hours when spinning 7s yarn from 45 bales of a mixing of American cottons, the variant being the settings of the draw-frame rollers. These were as follows (S=staple length of cotton):—

	Usual.		1st Alternative.		2nd Alternative.
Front to 2nd ...	$S + \frac{1}{16}$ in.	...	$S + \frac{1}{16}$ in.	...	$S + \frac{1}{16}$ in.
2nd to 3rd ...	$S + \frac{1}{16}$	...	$S + \frac{1}{16}$	...	$S + \frac{1}{16}$
3rd to back ...	$S + \frac{3}{8}$	...	$S + \frac{1}{4}$	...	$S + \frac{1}{8}$

The roller diameters from front to back were 1½, 1½, 1½, 1½ ins. Other machine particulars are fully recorded. The average numbers of "ends down" per 1,000 spindle hours were 32.4, 24.9 and 20.8 for the usual and the 1st and 2nd alternatives, respectively. C.

### (B)—SPINNING AND DOUBLING

**"Accotex" Roller Covering.** Armstrong Cork Co. Inc. *India-Rubber J.*, 1944, 106, 705. An announcement of a new material for roller covering, made of a mixture of cork and synthetic rubber. It is not thermoplastic and resists sticking, flattening, dye liquors, and solvents. It may be buffed again three or four times when worn. It is seamless and is fixed to the rollers by glueing. C.

## PATENTS

**Wool Combing Machines.** Taylor, Wordsworth & Co. Ltd. and F. Denham. B.P.560,991 of 1/5/1944. The revolvable large and small circles of a Noble or similar wool comb are heated by means of electrical elements located in stationary annular housings disposed below each of the gear wheels supporting the circles. W.

**Cork Spinning Roller Cot: Production.** Armstrong Cork Co. U.S.P.2,336,193. A mixture of granulated cork and binder is extruded into roller cots having a density of 26 lb. per cubic foot or more. C.

**Spinning Spindle.** H. & B. American Machine Co. U.S.P.2,336,593. The spindle is fitted with resilient means that permit a limited downward movement of the bolster to compensate for the gradual descent of the blade into the bolster case as the friction member between the whorl and the flange wears away. C.

### 3—CONVERSION OF YARNS INTO FABRICS

#### (A)—PREPARATORY PROCESSES

**Silk Hosiery Yarn: Preparation.** G. A. Urlaub. *Amer. Dyes. Rept.*, 1941, 30, 206-210. Differences between deliveries of silk, such as differences in denier and in gum hardness, and their effects on subsequent processes, particularly boiling-off and dyeing, and on finished products are discussed. The importance of not mixing different lots is emphasized. Soaking, winding and coning operations are discussed and the causes and prevention of various faults considered. Softeners, lubricants and other materials put on by throwsters and knitters are mentioned. These must be removed from silk hosiery in the boil-out prior to dyeing, and it is suggested that dyers should be supplied with details of the yarn construction and preliminary treatment in order to facilitate the determination of the most suitable boil-off and dyeing procedures. The processing of nylon yarn is briefly considered in relation to the dyeing of nylon hosiery. C.

#### (C)—WEAVING

**Cotton Crêpe Fabrics: Weaving.** *Textile Weekly*, 1944, 33, 954-960. Practical hints are given on the choice of the loom and reed and on setting the various mechanisms for weaving cotton crêpes. C.

**Loom Driving Belts: Management.** *Textile Weekly*, 1944, 34, 112-116. Practical hints are given on the arrangement and care of belts for the ordinary and half-cross drives. C.

**Looms: Maintenance.** E. L. Frankl. *Cotton (U.S.)*, 1944, 108, No. 4, 101. The writer advocates a system of loom overhauling in which, instead of completely dismantling and reassembling the loom at intervals of some years, the mechanism is dealt with sectionally, closely associated parts being overhauled by separate teams at regular intervals. It is claimed that more uniform settings are thus achieved and the looms are kept in good order with a minimum staff. C.

#### PATENTS

**Resilient Pile Fabric.** Boothroyd Rugs Ltd. and J. I. Boothroyd. B.P.561,805 of 26/10/1942:6/6/1944. A resilient fabric comprises two ground cloths spaced apart from one another and interconnected by pile threads constructed from resilient fibre, e.g. mohair, crossbred wool, or resilient rayon, which cross one another between the ground cloths and are interwoven with the threads in a W or M formation, the object being to produce a combination of thread groupings which will give a maximum cellular construction. For this purpose a pile fabric woven double or face to face on a double shuttle, double plush loom has one pile thread of two crossing pile threads, or one group of pile threads of two crossing groups of pile threads passing over one pick, under two picks and over one pick in the ground cloth, then under one pick, over two picks and under one pick in the other ground cloth, and repeats this sequence in regular order, the other crossing pile thread or group passing under one pick, over two picks and under one pick in the lower ground cloth, then over one pick, under two picks and over one pick in the upper ground cloth. The crossing pile threads in one row alternate with those in the next row, each pile thread being composed of a number of threads or strands of resilient fibres or filaments, the crossing pile threads passing in opposite directions between the same picks in the two ground cloths, thereby obtaining a double number of threads or strands at each crossing. C.

**Shuttle Tongue.** Kirk & Co. (Blackburn) Ltd., H. Wrigley and F. Haworth. B.P.561,847 of 24/11/1942:7/6/1944. A shuttle of the type having a short metal peg, which is rigidly secured in the head and projects into the pirn or bobbin, is provided with pirn or bobbin retaining means comprising a cup slidably mounted on the peg into which the flanged base of the pirn or bobbin fits, the sides of the cup being so shaped in relation to the base of the pirn or bobbin that there is no relative rotary movement between them, a two-armed clip secured to the head of the shuttle, the arms of which enter the groove behind the flange on the base of the pirn or bobbin, two diametrically opposite

edges of the cup being formed with projections adapted to enter holes or slots in the arms of the clip when the pirn or bobbin is in the weaving position to prevent rotation of the cup on the peg, and a spring holding the cup against the arms of the clip to retain the projections in the holes or slots in the arms but against the pressure of which the cup can be pressed back to release the projections and allow the cup and pirn or bobbin to be rotated on the peg for removal of the former from the latter. C.

**Circular Knitting Machine.** R. Kretser (U.S.A.). B.P.561,907 of 25/9/1942: 9/6/1944. Circular knitting apparatus combines a needle bed, cam means for raising selected needles to latch clearing position, the cam means and needle bed being movable relative to one another, stationary yarn guiding means for feeding yarn exclusively to the selected needles raised by the cam means, and cam means and yarn guides for raising and feeding other selected needles in latch clearing position arranged in fixed relation to the first cam means. A spool rack and associated series of yarn spacing and guiding means may be provided, wherein each series of yarn guiding means lies in a straight row which is at a relatively small angle to an intersecting radius of the needle cylinder. This arrangement makes possible the production of a knitted fabric in which all the stitches in a large and commercial width fabric may comprise a mixture of coursewise and vertical or wale-wise stitches staggered in diagonal or herringbone or basket stitch formations. C.

**Cemented Pile Fabric Yarn or Fibre Supplying Mechanism.** M. Strode. B.P.562,086 of 16/7/1942:16/6/1944. Mechanism for supplying a warp of yarn or bat of unspun fibres comprises a clamping device through which the yarn passes, means for opening and closing the device to grip and release the yarn, a device to draw yarn from a supply and form a first loop in advance of the clamp as the latter grips the yarn, a second loop-forming device on the opposite or delivery side of the clamp and means for actuating the second device to draw yarn from the first loop through the clamp as the latter releases the yarn so as to form a second free loop or slack supply of yarn on the delivery side of the clamping device. Each loop-forming device may be in the form of a bail, and the bails so actuated that after forming their respective loops each will recede leaving a free loop and thus forming a slack supply of yarn on the delivery side of the clamp. Details are given of a form of yarn supply mechanism designed for use with an apparatus for making cemented pile fabric. C.

**Weft Replenishing Loom.** W. W. Triggs (Crompton & Knowles Loom Works). B.P.562,167 of 23/7/1942:21/6/1944. In a weft replenishing loom having a reserve bobbin magazine and a shuttle box adapted to be located in high or low position, the mechanism for effecting transfer from the magazine to a shuttle box includes a normally inactive setting member such as a latch movable to transfer position at a given level relatively to the magazine incidental to an indication of weft exhaustion by the weft detector, and a transfer bunter on the shuttle box movable forwardly toward the latch when it and the shuttle box are in the same high or low position and the latch is in transfer position, to operate the same, but movable forwardly along a path below the latch so as not to operate the same when the transfer mechanism is in high position and the shuttle box is in low position. C.

**Composite Fabric: Weaving.** E. Glendinning and F. Binns. B.P.562,185 of 3/12/1942:21/6/1944. A composite fabric comprises a warp and weft woven cloth formed into a succession of transverse folds (preferably closely spaced or of relatively small pitch to afford one another mutual support) and intersected longitudinally by warps of a ground forming cloth lying substantially in one plane, a weft or wefts of which pass between each or certain of the convolutions of the folds. The amplitude of the fold convolutions may be symmetrical on both sides of the ground cloth or warps or the amplitude of the fold convolutions may be greater on one side than the other of the ground cloths or warps, including the case where the folds are of minimum amplitude and lie substantially in contact with the ground cloth or warps. Groups of folds of substantial amplitude may be separated by folds of smaller amplitude. The folds may be intersected on one or both sides of the plane of intersection by the ground forming cloth by additional warps or woven warps and wefts which may be located in a plane (or planes) at the tops of the folds or loops of the folding cloth or

intermediate the tops and the ground forming cloth. Instead of a single ground forming cloth the composite fabric may comprise a pair of woven ground forming cloths one on each side of the central plane of the composite cloth and intersecting the folds of the folding cloth. Independent weft threads or filling of substantial gauge may be introduced between or within the fold loops. Yarns of animal, vegetable or mineral origin or mixtures thereof may be used. The method of weaving is explained. Padding material comprises superposed layers of the composite fabric secured together by adhesives or by quilting or stitching.

C.

**Weft Replenishing Loom.** W. W. Triggs (Crompton & Knowles Loom Works). B.P.562,193 of 23/7/1942:21/6/1944. A weft replenishing pick and pick weft mixing loom having a gang of two shuttle boxes which shifts in a four-pick cycle is provided with means adapted to move the upper shuttle box to inactive position during the first pair of picks and to move the upper shuttle to active position during the second pair of picks of the same four-pick cycle, a reserve bobbin magazine, an actuator having successive cycles of movements each cycle of which is completed within two successive picks of the loom, a weft detector to indicate exhaustion of weft in the shuttle in the upper shuttle box during the first pair of picks of a four-pick cycle, weft replenishing mechanism actuated under control of the actuator in co-operation with the weft detector, and adapted, when the weft in the shuttle is exhausted, to be actuated to effect replenishment of the shuttle in the upper shuttle box from the magazine during a replenishing operation which is initiated and completed in the first pair of picks of the four-pick cycle, and means adapted to prevent the actuation of the replenishing mechanism during the second pair of picks of the four-pick cycle. The means preventing co-operation between the actuator and the weft detector may comprise means for locking the feeler against action during the second pair of picks, thus enabling the magazine to be used for automatic weft mixing although controlled by a cam which completes its cycle of operations in two picks.

C.

**Straight-bar Heeling Machine.** W. Cotton Ltd., G. Wilders and J. E. Lynam. B.P.562,213 of 19/12/1942:22/6/1944. A straight-bar heeling machine is provided with a needle bar comprising two pairs of parts each consisting of an inner and an outer part equipped with needles, and a pivotal mounting for each outer part wherein the part is movable between a folded running-on position in which it is located at the back (i.e. that side whereat the hooks of the needles are normally presented in a straight-bar knitting machine) of the adjacent inner part with the needles of the two parts in parallel lines, and an extended position in which it is aligned at the outside of the adjacent inner part, and preferably with the needles aligned with those of the inner part. With advantage, locking means are provided for locating the outer parts in the extended position. Such a machine is adapted to knit a heel tab on to one high heel part of one stocking blank by the employment of one of the pairs of parts and to knit another heel tab on to the opposite high heel part of a second stocking blank by the employment of the other pair of parts. Heel tabs are then knitted on the other sides of the blanks.

C.

**Multiple Box Loom Idle Weft Gripper.** Henry Owens & Co. Inc. U.S.P. 2,336,118. The claim is for a set of grippers, each with a fixed and a movable part, which are attached to the ends of the various compartments in a vertical multiple box loom to hold the weft from the idle shuttles against entering the warp shed.

C.

**Loom Picker Lubricating Device.** Crompton & Knowles Loom Works. U.S.P. 2,336,187. The picker spindle has a lubricant bore with lateral outlet connected to the rear outlet in a flared guide carried on the sley. The oil can is held to this flared guide as the sley advances.

C.

**Weft-replenishing Loom Revoked Thread Remover.** Crompton & Knowles Loom Works. U.S.P.2,336,255. The claim is for a thread placer that forms a visible loop in the weft between it and the adjacent selvage of the cloth if the weft replenishment has been revoked through the shuttle being improperly placed.

C.

**Weft-replenishing Loom Pneumatic Thread Removers.** Crompton & Knowles Loom Works. U.S.P.2,336,320/1. The claims are for thread placer mechanism to lift the weft that is due for transfer against the intake mouth of a device into which the weft is sucked by means of an air current.

C.

**Centre Weft Fork Stop Motion.** Draper Corporation. U.S.P.2,336,343. A centre weft fork is actuated by a rod that has a cam for lifting the fork when moved in one direction, a stop to prevent lengthwise movement in the other direction if weft failure occurs, and a guide to prevent rotation of the rod. C.

**Knitting Machine.** Vanity Fair Mills, Inc. U.S.P.2,336,455. The claim is for a knitting machine comprised of slotted needles, guides for placing the thread in the slots, awls, loopers, stationary guides for receiving and directing these various parts, and means for operating them in knitting sequence. C.

**Loom Temple.** Draper Corporation. U.S.P.2,336,591. The bottom part of the temple to which the pod is secured, and the top part above the pod, both end in vertical pieces that lock together by a screw thread device so that the height of the temple top above the pod can be adjusted. C.

**Loom Picking Motion.** Crompton & Knowles Loom Works. U.S.P.2,336,876. A pair of links are connected at the point where they join to the two picking sticks. The two links in each pair are normally at an angle to each other but means operated from the sley tend to bring them into line and thereby impart picking strokes. C.

**Self-threading Shuttle.** Steel Heddle Manufacturing Co. U.S.P.2,336,937. The shuttle is fitted with a threading block, cast as a single piece from hard metal and having a tapered horn extending into the thread channel from one side wall. The horn extends below the level of the axis of the yarn channel, then backwards and inwards. C.

#### 4—CHEMICAL AND FINISHING PROCESSES

##### (B)—BOILING, SCOURING, DEGUMMING AND WASHING

**Wool Scouring Machinery: Future Developments.** W. H. Robinson. *Wool Rec.*, 1944, 65, 930-932. Improvements so far achieved in automatic wool scouring machinery are briefly listed, and future requirements suggested. The factors which prevent the development of the solvent system should be investigated. In the emulsion system, improvements are suggested in automatic feeding, bowl cleaning, rake motions, squeeze rollers and liquor control. W.

##### (D)—MILLING

**Milling and Scouring Flannels and Felts.** D. R. H. Williams. *Wool Rec.*, 1944, 65, 757-759; *Text. Mfr.*, 1944, 70, 266-267. All-wool flannel, 17/18 oz., was treated in the Williams-Peace combined milling and scouring machine. The time taken was 41 min. per piece with 4 pieces in the machine (total time 2 hr. 45 min.) and 180 lb. weight on the trough lid, compared with 1½ hr. for milling and nearly 1½ hr. for scouring and washing-off 2 pieces when each process was done in a separate machine. For the production of commercial felts on the combined machine, reference is made to a previous article (these *Abs.*, 1944, A 294). W.

##### (I)—DYEING

**Cotton Hanks, Braid and Tape: Dyeing.** A. Ellis. *Textile Weekly*, 1944, 34, 26-32. Practical hints are given on the production of level dyeings on cotton yarn in the form of hanks, braid or tape by means of gravity percolation machines of the Rhodes and Simplex types. C.

**Hosiery: Dyeing.** C. H. Asbury. *Amer. Dyes. Rept.*, 1941, 30, 204-205, 210. A discussion of the use of developed, sulphur, naphthol and vat dyes for the dyeing of hosiery, the value and limitations of each type, suitable dyeing procedures and necessary precautions. C.

**Nylon Gloves: Dyeing and Finishing.** J. C. Broadmeadow. *Amer. Dyes. Rept.*, 1941, 30, 193. Knitted nylon gloves combine the advantages of light weight, unusual strength, remarkable elasticity, and the desirable property of returning to the original shape after washing. Some acid dyes can be used for nylon but acetate rayon dyes are preferred. Prior to dyeing, nylon piece goods are first scoured at 140° F. with soap and mild alkali, extracted lightly, tenterd, rolled on a perforated roll, and pre-boarded in a steam chest at a temperature higher than any of the subsequent operations and in the same shape as that desired for the finished product. In dyeing it is necessary to submerge the cloth beneath

the dye liquor at some point to obtain an even dyeing. The dye bath contains the same assistants as are used in scouring. The dye is entered in a warm bath, raised to 140° F. for 20 min., then to 190° F. for 40 min. The bath is cooled to 160° F. for additions. C.

**Silk Hosiery: Dyeing.** *Amer. Dyes. Rept.*, 1941, 30, 211-214. The split bath method of dyeing silk hosiery is studied and the pH range of the entire procedure analysed. The split bath method is claimed to be superior to the single or double bath methods in so far as the quality of finished products is concerned. C.

**Direct Dyes: Alkaline Reduction During Dyeing.** A. Carbone. *Amer. Dyes. Rept.*, 1943, 32, 415-418. In the dyeing of wool and cotton mixture army hose with a mixture of Diamine Fast Blue FFB, Chloramine Yellow and Pyrazol Fast Orange RL the shade increased in redness during dyeing. It was found that the stockings contained residual alkali and since dyeing was carried out in the wetting-out bath, the alkali was present during dyeing. The change in shade could be prevented by adding ammonium sulphate to the dyebath. The original colour change was considered to be due to the presence of alkali and of potential reducing agents such as cellulose and wool. Tests were made of the dyeing of cotton, wool and rayon yarns with Diamine Fast Blue FFB and numerous other dyes, with and without additions of soda ash, ammonium sulphate and sodium chlorite to the dyebath. The results confirm the view that irregularities in dyeing of the type described above are due to alkaline reduction. Direct dyes of the fast-to-light group are particularly sensitive to this type of breakdown. The trouble can be eliminated by controlling the alkalinity of the dyebath and this is best accomplished by the addition of ammonium sulphate. Cotton is less active than viscose rayon and wool in bringing about dye reduction in an alkaline dyebath. C.

**Dyes and Finishing Agents: Substantivity** A. M. Schwartz. *Amer. Dyes. Rept.*, 1944, 33, 164-168. A discussion of substantivity or affinity for cellulose, the mechanism of dyeing, the substantivity of water-soluble direct dyes, water-insoluble dyes and finishing agents, the relationship between the substantivity of dyes and the adhesion of finishing materials to the surface of fibres, and developments in permanent finishes that may be expected as a result of research on synthetic resins and coating materials. C.

**Wool Dyeing: Avoidance and Correction of Faults.** F. Townend. *J. Soc. Dyers & Col.*, 1944, 60, 144-148. The effects are discussed on the dyeing properties of wool of carbonising, peroxide bleaching and sulphur stoving which decrease the affinity (light-dyeing damage), and of setting and anti-shrink processes and damage by alkali, mildew and exposure to light which increase the affinity (heavy-dyeing damage). Methods are suggested for avoiding and correcting uneven dyeing due to improper control of these prior processes, special attention being drawn to the use of hydrogen peroxide in modifying the dyeing affinity of wool. The use of mixtures of chlorinated and normal wool, in which novel effects may be produced by taking advantage of the changed affinity for dyes or of differential shrinkage in milling, is discussed. W.

**Dyeing Worsted Yarn with Chrome Colours.** "Concord." *Text. Merc.*, 1944, 111, 41-42, 67-69. General methods for dyeing by the metachrome and afterchrome processes are given, with detailed suggestions for producing shades in brown, blue, black, green and red. W.

#### (J)—PRINTING

**Printing and Finishing Processes: Modern Trends.** R. W. Jacoby. *Amer. Dyes. Rept.*, 1941, 30, 170-178. Recent developments in printing and finishing processes, including pigment printing, the urea process for the printing of acid and direct dyes on rayon and cotton, conversion printing, and the use of resins for crease-, shrink- and slip-proofing, for improving fastness to washing, and for modifying handle, are discussed. Disadvantages associated with the use of resins, e.g. their effects on the shade and light fastness of certain dyeings, the development of odours, the formation of chloramine on treatment with chlorine in laundering, and the possibility of dermatitis, are pointed out. C.

## (K)—FINISHING

**Cellulosic Fibres: Acid Dyeing and Animalizing.** *Amer. Dyes. Rept.*, 1942, 31, 494, 509-511. The constitution and properties of silk and wool are briefly discussed, and methods of animalizing or basifying cellulosic fibres with the main object of imparting affinity for acid dyes are reviewed. The nature and characteristics of casein, nylon, Vinyon and Rayolanda fibres, and their affinities for the various classes of dyes are discussed. C.

**Nitroparaffins and Derivatives: Use in Textile Processing.** H. Robinette. *Amer. Dyes. Rept.*, 1942, 31, 575-580. A discussion of the physical properties of nitroparaffins and their derivatives, such as nitrohydroxy and aminohydroxy derivatives, soaps, ester-amides, ester-amines, oxazolines, etc., made from the aminohydroxy compounds and fatty acids, amino dioxanes and other products, and their uses as solvents, wetting, scouring, emulsifying, degumming and finishing agents, kier-boiling and mercerising assistants, and as intermediates in the synthesis of various products used in the textile industry. C.

**Cation-active Softening Agents: Analysis.** See Section 5D.

**Glass Cloth Laminated Plastics: Production.** H. W. Collins. *Modern Plastics*, 1944, 21, No. 9, 104-106. Laboratory techniques for the production of small experimental quantities of glass-reinforced, low-pressure laminates are described. The production involves impregnation of the glass cloth with the resin and building-up of the laminates, followed by curing between glass plates under pressure in an electrically-heated oven. Various methods of impregnation are described and curing schedules for laminates impregnated with various resins are outlined. C.

**Glass Fibre for Plastics Reinforcement: Forms, Properties and Handling.** G. Slayter. *Modern Plastics*, 1944, 21, No. 9, 100-103. The forms of fibrous glass chiefly used as reinforcement for low-pressure plastics are continuous filament, all-glass cloths and warps; uni-directional cloths, i.e. cloths with a glass warp and cotton weft; and glass fibre flock. Glass fibres are characterised by high strength, elasticity, stability and resistance to fire, mildew, etc. In the production of glass cloth the fibres are lubricated with a mixture of dextrinised starch, oil, gelatin, neutral emulsifier, complex amine salt and polyvinyl alcohol. To obtain satisfactory adhesion between the resin and the glass fibres, certain of these ingredients must be volatilised and others must be modified but retained on the fibres. The change is best effected by heat treatment which fixes a starch-gelatin film on the fibres, thus providing a firmly anchored base for adhesion with the resin. Methods of heat treatment are briefly described and necessary precautions are pointed out. Methods of applying the glass fibre reinforcement vary according to whether the material is to carry tensile or compressive forces, or both. The different arrangements are outlined. The modulus of elasticity of glass reinforced plastics is affected by condition of cure of the resin, fibre diameter, closeness of weave and direction of fibres, and by the glass-to-resin ratio. C.

**Fabrics: Testing Handle and Effect of Finishing Treatments. Resin-finished Rayon Gabardines: Colour Fastness, and Physical Properties.** See Section 5C.

**Persian Lambskin Pile Fabric: Processing.** S. Wouble. *Text. Col.*, 1944, 66, 95-96. The operations are described of desizing, scouring, batting-up and pile formation, dyeing, and final batting-up and dressing of the pile. W.

**Wool Fabrics: Chemistry and Practice of Finishing.** C. S. Whewell. *Text. Rec.*, 1941, No. 702, 25-27, No. 703, 33-34, No. 704, 29-32, No. 705, 37-41; 1942, No. 706, 26-29, No. 708, 35-37, No. 710, 33-36, No. 713, 35-38; 1943, No. 720, 38-42, No. 722, 43-46, No. 729, 50-52. The theory and practice of the finishing of wool fabrics are described in the light of recent mechanical and chemical developments. These articles deal with the constitution of the wool fibre and its physical and chemical properties, preliminary operations on the woven fabric (weighing, measuring, labelling, perching, knotting, mending and burling), fabric scouring (fundamental principles and theory, manufacture and properties of soaps, synthetic scouring agents, scouring machinery and scouring methods and defects), and factors affecting shrinkage during milling. W.

## (L)—PROOFING

**"Compar" Polyvinyl Alcohol Resin: Characteristics and Uses.** Resistoflex Corporation. *British Plastics*, 1944, 16, 260. A table is given showing the characteristics and the effects of various solvents, gases, and ageing on the transparent, flexible, rubber-like compounded polyvinyl alcohol resin, Compar. It is claimed that this product is 20 times more wear-resistant than natural rubber and the most solvent-proof rubber substitute yet developed. It can be milled like rubber but need not be vulcanized. Various uses are mentioned. C.

**Haydenite Resins: Use in the Production of Raincoats.** Stanley Chemical Co. *Rubber Age*, 1943, 52, 403 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1943, 830). Haydenites of the thermoplastic resin type are applied to fabric on ordinary rubber spreaders or pyroxylin coating machines which permit the spreading of successive coats under a doctor knife. In general, for fabric coated on one face, the application of 5 or 6 coats of the base coat and one or two of the finish coat will produce the most satisfactory results. A finished dry weight of 2.8-3.2 oz. per sq. yard is recommended. After the first, second or third coat of base coat, a facing calender is applied to the cloth. The air drying material requires no curing operation. Fabrics and garments of extreme lightness and pleasing appearance which meet the requirements of American specifications for service raincoats can be produced. Fabrics coated on both sides have lower tearing strength and resistance to low temperature cracking but provide the possibility of cementing face to back seams without application of cement. The face of the fabric is finished first and the necessary number of coats then applied to the back. In general, two coats with a thin knife, providing approximately 0.75 oz. of dry weight, will be satisfactory. Notes are given on the cementing of seams. C.

**Dihydroxyhexachlorodiphenylmethane: Application in Antiseptic Textile Materials.** R. A. Engel and W. Gump. *Amer. Dyes. Rept.*, 1941, 30, 163-165. An antiseptic is defined as a germ-killing or inhibiting agent intended for use on living tissues, and the agar-plate method of testing antiseptic materials is described. The characteristics required in an antiseptic for application to textile materials are outlined and it is claimed that there is no product available which meets all the requirements. Dihydroxyhexachlorodiphenylmethane fulfils most of the requirements though it is not soluble in acid solution and is removed by laundering and dry cleaning. Agar-plate tests have been made on samples of woollen, silk, cotton and rayon materials treated with this compound alone and in combination with finishing agents, such as synthetic resins and sulphonated tallow, oil, and fatty alcohol. Results of these tests and strength tests are tabulated and discussed. A clear zone of inhibition surrounded all specimens which had been treated with the antiseptic but not the untreated controls. Sulphonated oils depressed the activity of the antiseptic whilst a sulphonated fatty alcohol increased it. For cotton, rayon and silk fabrics treatment with a 0.1 per cent. solution, and in many instances 0.05 per cent. solution, of the agent is sufficient. Woollen goods appear to require 0.1 per cent. or more. This compound has no effect on the tensile strength of the textile materials. C.

**Insulating Tape: Production.** C. C. Downie. *Textile Weekly*, 1944, 34, 22-4. A brief account of the varnishing of unbleached cotton cloth and cutting it into tapes for electrical insulation. C.

**Textile Fibres: Microbiology.** See Section 5A.

**Flame-proofed Cotton Fabric: Deterioration. Mildew-proofed Materials: Analysis for Copper.** See Section 5C.

## PATENTS

**Chlorite and Hypochlorite Bleach Liquor: Application.** Mathieson Alkali Works (New York). B.P. 561,834 of 24/7/1942: 7/6/1944 (Conv. 8/8/1941). Cellulosic textile materials are bleached by treatment with an alkaline solution of sodium or other alkali metal chlorite and a hypochlorite. The ratio of hypochlorite to chlorite is preferably  $1\frac{1}{2}$ :1 based on the available chlorine. The pH of the solution should be between 8.7 and 10.0, and the total available chlorine 1 to 3g. per litre. Oxycellulose formation is less with this process than with the ordinary hypochlorite bleaching, whilst the bleached products are of equal or superior whiteness. C.

**Composite Waterproof Fabric: Production.** R. & J. Pickles. B.P.561,906 of 24/9/1942:9/6/1944. A waterproof sheet material is made by amalgamating, e.g. by calendering together under pressure, a number of sheets of hessian cloth which have previously been prepared by coating with a mixture of plasticised nitrocellulose and linseed and/or castor oil, the proportion by weight of oil being not less than that of nitrocellulose. The coating mixture may also contain fillers and pigments. C.

**Sulphonated Phosphonic Acid Surface-active Agent.** Eastman Kodak Co. U.S.P.2,336,230. The claim is for agents of the formula  $(OH)_2PO \cdot CRR' \cdot O \cdot SO_3H$ , where R and R' are H, alkyl, aryl, naphthenyl or alkaryl. C.

**Window Shade Fabric: Finishing.** E. I. Du Pont de Nemours & Co. U.S.P. 2,336,265. A non-tendering window shade fabric has a coating of cellulose nitrate, a plasticizer and a pigment, at least 20 per cent. of which is zinc oxide having particle dimensions greater than  $0.4\mu$  but less than  $3.2\mu$  in any one direction. C.

**Aeroplane Fabric: Finishing.** E. I. Du Pont de Nemours & Co. U.S.P. 2,336,266/7. (1) A supple, coated fabric having a potential width-way shrinkage of 5-15 per cent. before coating is obtained by thoroughly wetting the fabric with water, allowing it to shrink 5-15 per cent., filling the interstices of the wet fabric with an emulsion of a cellulose derivative in which there is a low proportion of plasticizer and water is the internal phase, drying and stretching to the original width so as to fracture the film minutely, and finally calendering the dry fabric. (2) The cellulose derivative is applied as a composition containing a volatile solvent. C.

**Plastics-coated Cotton Fabric: Printing.** E. I. Du Pont de Nemours & Co. U.S.P.2,336,365. Cotton fabric is coated with a permanent finishing agent selected from alkyl acrylate or methacrylate polymers, alkali-soluble alkyl celluloses, deacetylated chitin, rubber, chlorinated rubbers, polyvinyl alcohols, co-polymers of vinyl chloride and vinyl acetate, and polyamides, and then printed with an alkaline type of paste, to give sharply registered designs. C.

**Cellulosic Fabric Dimension-stabilizing and Dye Affinity-modifying Agent: Application.** Rohm & Haas Co. U.S.P.2,366,340/1. (1) The fabric is impregnated with a solution containing 5-15 per cent. of a compound  $(RO \cdot CH_2 \cdot NR_2 \cdot R_3 \cdot CH_2 \cdot OR_1)_X$ , dried under conditions to secure the desired dimensions, and heated to cause reaction with the cellulose and elimination of nitrogenous compounds; R is an alkyl radical with 2-10 C atoms,  $R_1$  is an alkyl, alicyclic or aralkyl radical with less than 12 C atoms,  $R_2$  and  $R_3$  are alkyl groups with 1-4 C atoms or are united into a ring with the N atom, and X is a salt-forming anion. (2) The above treatment is also claimed as a means to reduce the affinity of cellulose for direct dyes and increase the affinity for cellulose acetate dyes. C.

**Mothproofing Textiles.** D. W. Jayne, Jr. (to Amer. Cyanamid Co.). Canadian P.415,273 of 21/9/1943 (through *Chem. Abs.*, 1944, 38, 1128). The textile is treated with a water-soluble guanidine salt of an aliphatic monocarboxylic acid, and then with a solution of a higher fatty acid salt, to precipitate a water-insoluble guanidine salt. W.

## 5—ANALYSIS, TESTING, GRADING AND DEFECTS

### (A)—FIBRES

**Textile Fibres: Microbiology.** W. S. Marsh. *Amer. Dyes. Rept.*, 1942, 31, 563-569. A report is given of a discussion of bacteria and fungi occurring on textile materials and their effect on the textile materials, the numbers of organisms per sq. in. commonly found on cotton, wool and silk, the use of ultra-violet radiation for the control of air-borne organisms, the treatment of textile materials with germicides and fungicides, and the effects of synthetic resins, formaldehyde, salts of heavy metals, and other compounds on the growth of micro-organisms. C.

**Wool Fibre: Structure; Electron Microscope Study.** C. W. Hock and H. F. McMurdie. *Amer. Dyes. Rept.* 1943, 32, 433-436, 451-454. A more detailed account is given of investigations which have been described elsewhere.

**Measurement of Damage in Wool Materials: Test for Estimating Small Amounts of Mechanical Modification.** C. S. Whewell and H. J. Woods. *J. Soc. Dyers & Col.*, 1944, 60, 148-151. A sample (approx. 0.1 g.) is extracted with alcohol and ether, and agitated for 15 min. at 20° C. in 100 ml. sodium hypochlorite solution (0.12 per cent. chlorine) at pH 10. It is washed for 1 min. in 5 changes of tap water (200 ml. in each case), and then stained with dilute Methylene Blue solution and finally examined under the microscope. Applied to wool samples (A) extracted with alcohol and ether (control), (B) scoured by hand, (C) carded and extracted with alcohol and ether, and (D) carded and scoured with dilute soap solution, the test shows a high degree of sensitivity since it reveals the small amount of mechanical damage which occurs during carding. A further advantage is that judgment is based not upon depth of staining, but upon the area stained. The results appear to be reproducible. It can be used either to obtain an absolute evaluation of the condition of a particular wool, or to estimate the amount of damage caused by processing or treatments. W.

**U.S. Dept. of Agric.: 1943 Wool Shrinkage Studies.** A. Johnston, W. M. Buck and G. C. Le Compte. *Natl. Wool Grower*, 1944, 34, No. 4, 17-20. During 1943, 100 individual clips and a few graded lines were sampled, using the coring machine (these *Abs.*, 1942, A 83). The samples were scoured and their shrinkages checked against those of 10-bag lots scoured by commercial scourers. The differences averaged only 1.115 per cent. Tables are given showing the range of errors for both core and estimated shrinkages. The results show that the core-sampling method for determining shrinkage is more accurate than that based on visual and manual examinations which involve human judgment only. W.

**Australian Merino Wools: Variability of Fibre Fineness.** W. R. Lang. *Pastoral Rev.*, 1944, 54, 138-139. 1,600 samples of Australian merino wool were measured for variability in the thickness of the composite fibres of a single staple. 250 measurements were made on each sample at  $\times 350$  under standard humidity conditions. Curves show the range and standard deviation for 3 wools of 21-22 $\mu$  mean thickness, and the distribution of ranges and standard deviations in various mean thickness groups. W.

#### (B)—YARNS

**"Grex" Yarn Count System: Advantages.** A. G. Scroggie. *Cotton (U.S.)*, 1944, 108, No. 3, 102-103. The author shows by examples the advantages of the "Grex" system in determinations of the weight of yarn in fabrics of stated construction, especially when different fibres are incorporated in the warp or weft. A graph is reproduced of cotton counts from 80 down to 10 and equivalent Grex numbers from 50 up to 550. C.

#### (C)—FABRICS

**Fabrics: Testing Handle and Effect of Finishing Treatments.** E. C. Dreby. *Amer. Dyes. Rept.*, 1942, 31, 497-504. The first part of this paper dealing with the use of the Planoflex friction meter and compression meter for the evaluation of the handle of fabrics has previously been summarised from another source. The second part describes the use of these instruments for determining the effects of finishing agents and processes. Planoflex measurements of cotton poplins treated with different concentrations of each of four softening agents, friction meter measurements on silk hosiery treated with softening agents and with a delustring agent, compression meter measurements on spun rayon twills with and without crease-resistant finishes, and measurements with all three instruments on plain finished and calendered cotton print cloths, cotton sheetings treated with a regular starch finish and a semi-permanent finish, before and after laundering, cotton print cloths conditioned at different atmospheric humidities, and wool-rayon suitings of varied compositions are recorded and discussed. C.

**Flame-proofed Cotton Fabric: Deterioration.** A. S. Tweedie and C. H. Bayley. *Amer. Dyes. Rept.*, 1943, 32, 427-428. Tests were made with a light cotton sheeting which was rinsed in water, dried, soaked for 5 min. in a solution of a flame-proofing agent, centrifuged, and ironed on a flat-bed household press. The flame-proofing agents were (1) borax + boric acid, (2) borax + boric acid + ammonium sulphate, (3) borax + boric acid + ammonium dihydrogen phos-

phate, (4) ammonium sulphate, (5) ammonium dihydrogen phosphate, and (6) ammonium sulphamate. Tables are given showing the changes in tensile strength and cuprammonium fluidity after 5 and 10 treatments, with intermediate washing. All the flame-proofing agents caused measurable losses in strength at the end of ten treatments. Increases in fluidity showed that chemical damage had occurred in all cases. Damage increased in the order 1, 3, 2, 5, 6, 4. C.

**Mildew-proofed Materials: Analysis for Copper.** C. L. Hoffpauir and R. T. O'Connor. *Amer. Dyes. Rept.*, 1942, 31, 395-398. Details are given of procedures for the determination of copper in proofed textile materials by (1) an iodometric titration method, and (2) a spectrophotometric method based on the measurement of the blue colour produced by ammonium hydroxide. Solutions for testing are prepared by digesting samples with concentrated nitric and sulphuric acids. Results are given of determinations by the two methods of copper in copper solutions, cellulose, cellulose to which known amounts of copper solution were added, and cotton osnaburg and burlap treated with copper naphthenate and other copper compounds. Good agreement is shown between the two methods. The volumetric method has proved satisfactory for routine examination of samples of ordinary size containing moderate amounts of copper (3-60 mg. of copper per gram of sample), and is rapid and accurate. The spectrophotometric method gives an excellent check on the volumetric method and is particularly useful when the size of sample is small or the percentage of copper is relatively low (minimum of 0.2 mg. copper). C.

**Resin-finished Rayon Gabardines: Colour Fastness and Physical Properties.** Hazel M. Fletcher, Wilda M. Hay and Andrea J. Surratt. *Amer. Dyes. Rept.*, 1942, 31, 489-493 and 514. Measurements were made of the effects of laundering and dry cleaning five and ten times on the colour, strength, extensibility and dimensions of samples of (A) rayon gabardines with urea-formaldehyde resin and (B) non-resin type finishes. Statistical analyses were made of the fading, breaking load and elongation, and shrinkage data. Results are tabulated and discussed. The (A) fabrics had a firmer handle than (B). Dry cleaning did not greatly affect the appearance of either group. The (A) fabrics became sleazy on laundering and some showed considerable yarn slippage after abrasion. The statistical analysis showed significant differences in colour fastness and physical properties favouring (A) over (B). Fading of (B) fabrics was greater than that of (A), and fading due to laundering was greater than fading due to dry cleaning. There were no significant differences of fading in the colours or in the light and dark shades of (A). In the (B) fabrics the browns and the light shades faded least. (A) gabardines were stronger than (B). Dry cleaning did not affect the breaking strength of either group. Laundering decreased the breaking strength of (B) but not of (A). Resin finishes increased wet breaking strength but not resistance to abrasion. Exposures for 80 hours to light decreased the breaking strength of (B) but not of (A). The extensibility of (B) was greater than that of (A). Neither dry cleaning nor laundering affected the extensibility. The (A) fabrics shrank less than (B). Shrinkage due to laundering was greater than that due to dry cleaning for (B) but not for (A). C.

**Textiles: Informative Labelling.** H. F. Herrmann. *Amer. Dyes. Rept.*, 1941, 30, 194-196, 217. Some scientific aspects of informative labelling are discussed. Retailers have suggested that a simple qualitative description of the article and a plain, honest appraisal of its contents and service properties are required. Some really pertinent data should be given to support the general statements though purely scientific data are more confusing than helpful to the general public. A list is given of types of standards and testing methods which have been established and are in use on a voluntary basis by American mills and merchants for the quality grading of their lines. Meaningless expressions relating to colour fastness are discussed and the need for standard tests is pointed out. Reference is made to legislation regulating the accurate labelling of materials with respect to fibre content and its probable extension to labelling with respect to colour fastness. C.

#### (D)—OTHER MATERIALS

**Cation-active Softening Agents: Analysis.** D. Geltner and W. W. Razim. *Amer. Dyes. Rept.*, 1942, 31, 409-412. Details are given of procedures for the analysis of cation-active softening agents which generally comprise either amido-

amines, imidazolines, oxazolines or amino-esters, neutralised with an appropriate acid. The method involves a preliminary examination, determinations of ash, alcohol extraction, and volatile matter (water, alcohol, organic acid, hydrochloric acid) and the isolation and identification of fatty acids and amines. C.

**Ethylcellulose Films: Properties.** E. E. Halls. *Plastics*, 1944, 8, 57-64 (through *Brit. Chem. Physiol. Abstr.*, 1944, BII, 133). Films of cellulose acetate and of ethylcellulose were exposed to the following ageing tests: immersion in water at room temperature, exposure to dry heat at 60°, and exposure to fluctuating conditions of warmth and dampness; in every case the weight and dimensions of ethylcellulose films changed less than those of cellulose acetate films. Physical and mechanical properties of ethylcellulose are recorded; it is stable under the influence of light and resistant to ageing, being superior to cellulose acetate and much superior to nitrocellulose in these respects. Ethylcellulose allows free passage to light, including ultra-violet light; stability to alkalis permits the use of the usual soaps and detergents for cleansing windows made of this thermoplastic. The chief advantage of ethylcellulose is that it is flexible at -40° C. Its toughness at these low temperatures is unequalled by any other plastic. A wide range of plasticisers are compatible, and ethylcellulose can replace acetate in almost all of the various applications of the latter. C.

**Woolled Sheepskins: Preservation.** R. F. Innes. *J. Int. Soc. Leather Tr. Chem.*, 1944, 28, 78-92. In works experiments sheepskins were stored after sprinkling with (1) common salt, (2) a mixture of common salt and alum, (3) a mixture of common salt and sodium fluoride, and (4) a mixture of common salt and sodium bisulphate (dry pickle), and after immersion in a solution of common salt and sulphuric acid (wet pickle). The dry pickle had the best preservative action over prolonged periods. Laboratory experiments were then made, using both brine and solid salt with a range of disinfectants. Sodium chloride mixtures, containing sodium fluoride, zinc chloride, naphthalene and sodium pentachlorophenate respectively, gave the best results, the extent of preservation being judged by determining the percentage of free fatty acid in the grease extracted from the skin. Further works scale experiments confirmed the good results obtained with mixtures containing zinc chloride or sodium pentachlorophenate. W.

## 7—LAUNDERING AND DRY-CLEANING

### (A)—CLEANING

**Cotton, Rayon, Silk and Wool Fabrics: Effect of Washing.** Florence B. Castonguay, Dorothy O. Leekley and Rachel Edgar. *Amer. Dyes. Rept.*, 1942, 31, 421-426, 439-440. A report is given of a study of the effect of repeated washing (10, 20, 30, 40 and 50 washings) with 0.5 per cent. neutral olive oil soap, silicated soap, or a sulphated alcohol in distilled water on fabrics of cotton, regenerated cellulose rayon, cellulose acetate rayon, silk, wild silk and wool. The fabrics were all analysed for weight, absorption of light, ash, strength and shrinkage; the cellulose acetate rayon was analysed for acetyl and the wool for total sulphur; the silks and wool were analysed for nitrogen and moisture, and the fabrics washed with sulphated alcohol and the wool washed with soap or silicated soap were analysed for sulphate sulphur. The results are given in tables. Large losses in weight of the cotton and wild silk fabrics were due to removal of size. The wool, silk and rayon fabrics increased in weight on washing. The unbleached cotton and regenerated cellulose rayon samples became whiter with silicated soap than with soap. The fabrics washed with sulphated alcohol developed a green tint, which was more pronounced in proteic than in cellulosic fibres and was traced to copper in the distilled water. Residual ash of the cellulosic fibres decreased and that of the proteic fibres increased upon washing with each detergent, the rise being greatest for wild silk and wool washed with silicated soap and least for wool washed with sulphated alcohol. Wet strength of all the fabrics was lowered by washing but only the silk washed with sulphated alcohol and the wild silk lost more than half their wet strength during 50 washings. With the exception of the wool fabric, shrinkage of each fabric with different detergents varied no more than the deviations of the yarns per inch of fabric; comparatively high warp shrinkage of the cotton fabric, weft shrinkage of the regenerated cellulose and silk crêpes, and warp stretch of the silk and wool fabrics were due to relaxation whilst much of the change in area of the

cellulose acetate rayon fabric was caused by its drying in hard creases. The values for the acetyl content of the washed cellulose acetate rayon suggested no change greater than experimental error. Lower and more nearly constant amounts of sulphate were sorbed from the sulphated alcohol by the silk and wild silk than by wool, none was taken up by the cellulosic fibres, and the wool washed with soap or silicated soap did not acquire any sulphate sulphur. The data show that a silicated soap is more destructive to wild silk but no more degrading to cotton, rayon, silk or wool than soap. C.

## 8—BUILDING AND ENGINEERING

### (A)—CONSTRUCTION AND MAINTENANCE OF BUILDINGS AND PLANT

**Cotton: Use in Concrete.** C. R. Platzmann. *Oel u. Kohle*, 1942, 38, 1193-1194 (through *Brit. Chem. Physiol. Abstr.*, 1944, B I, 169). Addition of 2 per cent. of cotton or asbestos fibre to concrete reduces its permeability to water. Plaster of Paris or calcium chloride is used to reduce the setting time of concrete. C.

**Phenolic Laminated Paper Boards: Preparation.** H. L. Cox and K. W. Pepper. *J. Soc. Chem. Ind.*, 1944, 63, 150-154. The preparation of reinforced plastics from paper and phenol-formaldehyde resin is described. The influence of various factors in the preparation of such materials on their mechanical properties is discussed. The resin solution should impregnate the paper thoroughly and uniformly. Close control of the drying process is essential and the impregnated paper should be dried as much as possible consistent with complete bonding during pressing. The optimum resin content is that which just fills the air voids in the paper at any given pressure. This optimum resin content is indicated by a maximum in the curve connecting density and resin content. Means of improving the shear strength parallel to the laminations are discussed. C.

**Lubrication of Valves.** G. H. Pearson. *Industrial Heating Engineer*, 1944, 6, 98-102. Much stiffness and premature wear in valves can be avoided by proper and adequate lubrication. Methods of lubricating several different types of valves and parts are illustrated and described (e.g. parts of screwdown stop valve, parallel slide valve, piston type throttle valve and so on). La.

### (C)—STEAM RAISING AND POWER SUPPLY

**Steam for Power and Process.** H. E. Partridge. *Industrial Heating Engineer*, 1944, 6, 108-111. The balancing of steam and power demands is discussed; examples taken from practice include a laundry, and a carpet factory. The heat balance for the latter is given and illustrated diagrammatically. La.

**Engine Fastenings.** E. Ingham. *Steam Engineer*, 1943, 13, 83-85. Many steam engine breakdowns are caused by the failure of the fastenings such as bolts, cotters and keys, particularly connecting rod, cross-head and piston bolts; cotters in pistons, piston rods, cross-heads air pump-buckets and rods; keys for flywheels. Regular inspection is essential to avoid this trouble and the article discusses the best methods of avoiding premature failure. La.

**Reducing Fuel Consumption.** S. N. Duguid. *Steam Engineer*, 1944, 13, 102-103, 122. Fuel economy is briefly considered under the following headings: lagging, eliminating air and water films, avoid unnecessary boiling, space heating, steam engines, general comments. La.

**Mechanism of Steam Formation.** W. Goldstern. *Steam Engineer*, 1944, 13, 108-110, 115. A theoretical consideration of the quantities of heat involved in steam formation by heating hot water and reducing the pressure on hot water. La.

**Entropy and the Steam Cycle.** "Vacuum." *Steam Engineer*, 1944, 13, 116-119, 149-152, 160. Carnots cycle is briefly considered and is then compared with the Rankine (saturated steam) cycle, the approach being mainly historical. Subsequently practical applications to efficiency calculations are discussed and the progress in thermal efficiencies of a number of power stations is examined. La.

**Planning Steam Generation.** F. D. Mosher. *Laundry Age*, 1944, May 1, 57-62. An article discussing the planning of efficient steam generating plant for post-war use. Mechanical stokers and automatic control have rendered hand-firing obsolete and full advantage should be taken of their superiority over the older methods. La.

**Boiler Feed Water Regulation.** H. Hillier. *Mech. World*, 1944, 116, 76-80. A long abstract of a paper read before the Institute of Marine Engineers in which boiler and feed system characteristics are discussed in relation to boiler feed water regulation. Boilers are divided into two types, namely, tank boilers (including Scotch, Cornish, Lancashire, Economic, etc.) and water tube boilers and the feed and pressure characteristics are illustrated by a diagram. Types of feed pump and their controls are analysed in tabular form and discharge pressure, capacity characteristics of several types are described and illustrated graphically. La.

**Vertical Boilers.** E. Ingham. *Dyer*, 1944, 92, 41-43. Advantages and types of vertical boiler are first described briefly and then defects, and their prevention and remedies are considered. The points covered include external corrosion, removal of ashes, leaks, etc. La.

**Boiler Efficiency.** C. F. Wade. *Industrial Heating Engineer*, 1944, 6, 31-33. A general consideration of boiler combustion efficiency, separating the chemical and physical conditions. General furnace conditions and flue gas analysis are discussed. La.

**Heat Transmission in Economisers.** W. Goldstern. *Industrial Heating Engineer*, 1944, 6, 57-60, 85-87. An economiser is installed in order to reduce the flue gas temperature and at the same time increase the feed-water temperature. The best method for comparing economisers is worked out and typical heat transmission curves are illustrated. La.

**Electrode Boilers.** *Industrial Heating Engineer*, 1944, 6, 93. A description of a modern installation of Bastian and Allen electrode boilers for factory heating and canteen requirements. 3-350 kw. units each evaporating 1,000 lb./hr. at 120 p.s.i. are installed, as well as an electrode water heater. La.

**Use of Flash Steam.** W. Broadbridge. *Power Ldy.*, 1944, 71, 93. An account of the flash tank installed in the Wardle dryer at the Watford Steam Laundry. La.

#### (D)—POWER TRANSMISSION

**Plastics Bearing Materials: Bearing Strength.** R. T. Schwartz and E. Dugger, Jr. *Modern Plastics*, 1944, 21, No. 9, 133-137, 180-184. For the determination of bearing strengths, the test specimen, which was 0.938 in. wide and  $\frac{1}{8}$  in. thick, and had a 0.250-in. diameter bearing hole and an edge distance of 2.5 times the diameter, was used as the centre plate in a 3-plate jig employing hardened steel pins to provide the bearing load, the jig being loaded in tension. Deformation was measured between points on a line with the loaded edge of the hole and points in the jig. Simultaneous readings of load and deformation were taken until 4 per cent. deformation of the hole diameter was reached, at which point the strain gauges were removed and the specimen loaded to failure. The loads were converted to bearing stresses by dividing them by the bearing area, i.e., the diameter of the hole times the thickness of the specimen. Bearing stress at which the bearing hole was deformed 4 per cent. of its diameter was determined from the curve of bearing stress plotted against deformation; ultimate bearing stress was calculated from the maximum load sustained by the specimen. Results are given for various plastic materials. The bearing strengths of the thermoplastic materials tested were considerably lower than those of the laminated thermosetting materials. A high-strength paper phenolic laminate had the highest bearing strength of all the materials tested. Bearing strength at 4 per cent. deformation of the hole diameter ranged from 4,000 lb. per sq. in. for a cellulose acetate butyrate material to 31,100 lb. per sq. in. for the paper phenolic laminate. No specific correlation was found between bearing strength and tensile or compressive strength. The failures at the ultimate bearing stresses for all specimens except compressed phenolic-resin-impregnated laminated maple were in tension across the hole. The specimens of the latter material failed in transverse tension by splitting lengthwise through the hole. The effects of hole diameter, edge distance and thickness, and the use of the bearing test data in design are discussed. C.

#### (F)—LIGHTING

**Bleaching, Dyeing, Printing and Finishing Mills: Lighting.** J. W. Howell. *Trans. Illum. Eng. Soc. (London)*, 1943, 8, 153-170. Flow charts for finishing sections of the cotton and woollen industries are given, and the individual pro-

cesses and their lighting requirements are discussed. In the cotton industry, illumination in the range 10-15 ft. c. is required for inspection (soft warehouse), hank, warp or piece printing, colour mixing, schreiner, yarn polishing, and cropping. Dye inspection, printing, and final inspection require 15-20 ft. c. For etching and engraving, burling and mending processes 25-50 ft. c. are required and over 50 ft. c. for perching. General requirements and suitable types of lighting for the various rooms and departments are indicated. C.

**Light and Vision.** Sir John Parsons. *Trans. Illum. Eng. Soc.* (London), 1943, 8, 99-109. A report of an address. The response of the eye to light, illumination and visual acuity, the influence of background, tests of glare, the colour of light, vision at low illuminations, vision and illuminating engineering, and the I.E.S. code are discussed. Reference is made to the aims and work of the Illuminating Engineering Society, and various problems requiring further investigation are mentioned. C.

**Low Pressure Fluorescent Lamps: Applications.** W. R. Stevens. *Trans. Illum. Eng. Soc.* (London), 1943, 8, 175-195. Diffusing reflector, specular reflector, spread reflector, prismatic and diffusing glass, and plastic fittings for 5 ft. fluorescent lamps, and fittings employing louvres, are discussed. The results of experimental studies of the effects on light output of variations in size and shape of diffusion trough fittings for single and multilamp systems are briefly considered. Colour characteristics and radiant heating and stroboscopic effects are discussed and their influence on installation design and on the suitability of the lamps for various purposes is indicated. A method of calculating the number of lamps required to produce a given illumination intensity is explained. Present applications of 5 ft. fluorescent lamps in offices, factories and workshops are described, possible future applications are mentioned, and the probable influence of fluorescent lighting on building design is briefly discussed. C.

**Windows: Area Calculations.** T. Smith. *Trans. Inst. Illum. Eng. Soc.* (London), 1943, 8, 110-118. Simple equations are given for the determination of the window area necessary to secure a given penetration of daylight into a room and for the determination of daylight contours. Evidence is presented to show that the results to which these equations lead are of good accuracy. The mathematical theory on which the equations are based is briefly explained. C.

**Windows: Sky Factor Value.** P. J. Waldram. *Trans. Illum. Eng. Soc.* (London), 1944, 9, 16-21. Methods of determining the sky factor value of windows are critically discussed. The advantages of graphs over tabulated data are pointed out. The setting out of sky factor contour plans is described and the effects of obstructions are considered. C.

#### (G)—HEATING, VENTILATION AND HUMIDIFICATION

**Air-conditioning Plant: Reduction of Noise.** A. J. King. *Engineering*, 1944, 157, 501-504. The various causes of noise from air-conditioning plant employing electric fans are analysed, the measurement of noise by means of instruments is explained, and measures for noise reduction are described. C.

**Dew-Point Hygrometer: Manipulation.** J. A. Van den Akker and W. A. Wink. *Science*, 1943, 97, 494. Condensation of water on the polished metal surface of dew-point apparatus can be more easily detected if a thin film of a wetting agent is applied to the surface, leaving, for example, a rectangular central region untouched by the agent, and all the film excepting an invisible layer is removed by rubbing with a clean cloth. Condensation of water upon the zone treated with the wetting agent immediately forms an invisible continuous film, whilst the condensation upon the central zone occurs in the usual manner. Because of the exceedingly narrow line of demarcation between the two zones, a difference in reflectance of the order of 1.5 per cent. can be observed by an experienced operator. C.

**Ventilation.** S. Smith. *Industrial Heating Engineer*, 1944, 6, 73-75. Some notes, by permission of the I.H.V.E., on air distribution, ventilation and unit heating. La.

#### (I)—WASTE DISPOSAL

**Trade Waste Waters: Treatment at Traders' Premises.** W. Scott and W. Foster. *Inst. Sewage Purification, J. and Proc.*, 1942, 186-195. A description

of experimental work in treating waste waters from felt manufacturing (re-organisation of an existing purification plant dealing with acid waste), tar distilling, mercerising, dyeing and finishing (reconstruction of an existing plant, including automatic pH recording and control of chemicals), and dyeing and milling of berets. W.

**Lanolin-resin Protective.** Ministry of Aircraft Production. D.T.D. 663, March, 1944. The specification covers a homogeneous solution of lanolin (D.T.D. 122B) and resin (D.T.D. 375C) in a mixture of pool spirit S.B.P. 3 and xylene (Brit. Standard Specification 458), with an approved oil-soluble dye. Particulars are given of the distillation range of the pool spirit, and of the method of determining the hardness of the material. It is suitable for application by brushing, dipping or spraying. W.

#### PATENT

**Dehumidifying Apparatus.** John B. Pierce Foundation. U.S.P. 2,336,456. The illustration shows a tube of hygroscopic, pervious material surrounded by a wider jacket, both provided with air inlet tubes at one end and exit tubes at the other. A gas burner is lit at the inlet to the pervious tube. This tube is also surrounded by a cooling coil to remove the latent heat of condensation. C.

### 9—PURE SCIENCE

**Fuel Gas Water Vapour: Determination.** R. J. Pfister and D. J. Kerley. *A.S.T.M. Bull.*, 1944, No. 127, 17-22. A technique is described for determining moisture in fuel gases, by means of the Evelyn photo-electric colorimeter. The analysis requires a sample of condensate frozen out at  $-70^{\circ}\text{C}$ . from a measured volume of gas. Enough gas is sampled to yield about 0.25 gm. of water. The amount of any non-aqueous diluent present in the sample is given by the difference between the weight of the condensate, after warming and venting to the atmosphere, and its approximate water content. To the condensate 25 ml. of the water indicator solution (0.1 per cent. cobaltous bromide in butanol) are added and the transmission is read in the Evelyn colorimeter at  $74.0^{\circ}\text{F}$ ., with the 660  $\text{m}\mu$  band filter. Three calibration graphs are used to correct, if necessary, the transmission of the indicator solution (1) for a slight deviation in temperature from the standard, (2) for non-aqueous condensate as indicated by the total weight of condensate, and (3) to convert the corrected transmission to water content of the gas sampled. Results from both field and laboratory tests indicate that water contents may be determined to within  $\pm 3$  per cent. of the absolute value of the moisture present. C.

**Soluble Phosphate and Silica: Determination in Water.** T. S. Harrison and H. Storr. *J. Soc. Chem. Ind.*, 1944, 63, 154-157. Controlled reductions of phosphomolybdate and silicomolybdate by quinol to molybdenum blue are used for the determination of phosphate and silica, each in the absence of the other, in water. Details of the procedures are given. Measurements on the blue solutions are made with the Spekker photo-electric absorptiometer. Conditions suitable for the determination of either radical in the presence of the other can be produced by adjusting the acid concentration. Some typical results are given and it is shown that very little interference is caused by the presence of various other ions in the water. Results obtained in 30 min. (or less) on a maximum sample of 40 ml. compare favourably with those given by the much longer gravimetric processes, which require large samples. A short absorptiometric study of the course of the phosphate reaction and the changes occurring when the order of the added reagents is varied is reported. C.

**Glutamic Acid: Determination in Proteins.** H. S. Olcott. *J. Biol. Chem.*, 1944, 153, 71-82. A method for the determination of glutamic acid in proteins is based on the measurement of the loss in amino nitrogen occasioned by the transformation of glutamic acid to pyrrolidonecarboxylic acid at  $125^{\circ}$  and pH 3.3. The glutamic acid is approximately 92 per cent. converted in 4 hours. Cystine interferes but when a suitable correction is applied the method can be used to estimate the amount of glutamic acid in protein hydrolysates. By the use of the Van Slyke manometric apparatus, the method is applicable to the determination of glutamic acid in 25 to 100 mg. samples of protein with an estimated accuracy of 5 per cent. Results obtained for egg albumin, zein, cottonseed

globulin, casein, gelatin, wool and feather keratins and various other proteins are compared with those of previous determinations by other methods. C.

**Oxygen: Determination in Organic Compounds.** P. J. Elving and W. B. Ligett. *Chemical Reviews*, 1944, **34**, 129-156. A critical review of methods for the determination of oxygen in organic compounds including methods based on complete oxidation, destructive chlorination, and reduction. C.

**Gluten Sulphydryl Compounds: Oxidation.** J. C. Baker, H. K. Parker and M. D. Mize. *Cereal Chemistry*, 1944, **21**, 97-107. With refined flours of widely varied strength, the SH values per gram protein ranged from 0.73 to 1.22 mg. for aqueous extracts; from 0.12 to 0.22 mg. for hand-washed glutens; and from 0.05 to 0.13 mg. for purified glutens. No consistent relationship was found between the SH content of the three flour fractions of various flours or between their SH content and gluten strength. A large fraction of the SH in the glutens could not be removed by repeated washings. Since added glutathione may be readily washed out, a considerable proportion of the sulphydryl groups of flour is apparently present in more complex cysteine combinations. These sulphydryl compounds do not appear to be an integral part of the molecular structure of the gluten proteins, since the SH content of the purified glutens varied widely. Treatment of flour with chlorine and nitrogen trichloride, mixing doughs in oxygen or with sodium chlorite, fermenting doughs with or without bromate, and natural ageing of flour lowered the SH content of water extracts and glutens prepared therefrom. The total decrease in SH which resulted from the flour treatments was equivalent to approximately 100 p.p.m. glutathione, a quantity which is sufficient to produce marked effects in bread making. Changes in gluten strength did not parallel the reductions in SH content due to oxidation. C.

**Hydrogen Bond: Importance in Textile Chemistry.** C. F. Goldthwait. *Amer. Dyes. Rept.*, 1941, **30**, 166-168. A general account is given of the part played by hydrogen bonds in the structure of cellulose and protein fibres, the formation of starch granules, the aggregation of direct dyes in solution, and the dyeing of cotton, wool, and nylon. The origin and rise of the hydrogen bond theory is briefly discussed. C.

**Cross-linked Polymers: Molecular Size Distribution and Gel Point.** W. H. Stockmayer. *J. Chem. Phys.*, 1944, **12**, 125-131. A statistical calculation of the gel point and of the molecular size distribution is made for cross-linked high polymers of arbitrary initial size distribution. The weight-average polymerization degree of the cross-linked polymer depends only on the weight-average polymerization degree of the initial polymer and the degree of cross linking. The results obtained also apply to certain vinyl-divinyl copolymers. Polymerization degrees can be estimated from observations of the gel point. C.

**Varnishes and Film-forming Solutions: Air Content and Degassing.** E. Manegold and F. Peters. *Kolloid Z.*, 1942, **101**, 1 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1943, 162). The liquid to be investigated was saturated with dry air at 20° and at a total pressure of 760 mm. Hg. A measured amount was placed in an apparatus evacuated to about 0.005 mm. Hg and the solvent was distilled into two liquid air-cooled traps. The air expanded in the evacuated apparatus, after removal of the last traces of solvent vapour by freezing, was collected in a burette by means of a Sprengel pump and its volume at 25° C. and 760 mm. Hg was read. Tables are given showing solids in weight per cent., specific weight of liquid, volume of gas dissolved in 100 c.c. liquid, partial pressure of air over liquid, and Bunsen absorption coefficient for various non-pigmented clear varnishes, pigmented varnishes, and nitrocellulose and cellulose acetate solutions. For degassing with ultrasonic waves the vessel containing the liquid was placed in a sound-conducting liquid of a quartz ultrasonic generator (350 kc, 180 watts), consisting of paraffin oil 5 cm. deep for 5 min. The volume of air freed was measured at 25° C. and 750 mm. Results for some of the varnishes and solutions are tabulated. C.

**Emulsions: Film Formation.** H. Wagner and A. W. Böhnisch. *Kolloid Z.*, 1942, **100**, 263 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1943, 162). A report is given of observations of the formation of films by oil-in-water and water-in-oil emulsions of linseed oil, chlorinated rubber, Bunalit, Acronal II, Plexigum KP, Mowilith N, and polystyrene. Testing of the optical properties, microscopic examination at a magnification of 100 in transmitted,

incident, and mixed light, and solubility tests in water and in benzene were performed on films obtained by spreading the emulsions on glass. A reversibility test was carried out on films on glass. Films produced on a zinc plate were tested for permeability to water by the cadmium test (1936). Thick films for cross-sectional examination by opaque illumination were obtained by repeated brushing of the emulsions on pasteboard primed with nitrocellulose varnish. For investigation of the absorption of the individual phases by the background the emulsions were spread on gypsum, on untreated pasteboard and on pine. Tables are given showing the characteristics of the various films. An attempt was made to classify the films according to the Manegold gel system. There are lamellar and fibrillar systems, as well as various mixtures of the two. Under special conditions corpuscular systems also occur. The lamellar system is the most suitable one. C.

**Plastics: Water Absorption; Determination by Beam Deflection.** J. Delmonte and L. Asselin. *Modern Plastics*, 1944, 21, No. 9, 138 and 188. Samples are cut to lengths of 5 or 6 in. and thicknesses of about  $\frac{1}{8}$  in. and coated along one side. The cut edges are then covered with a thin moisture-impervious film of metal, 1 mil thick, which is held in place by a thin adhesive coating not chemically reactive with the plastic. The entry of moisture is thus limited to one side. The specimen is supported as a cantilever and immersed in water, and the movement of the end of the beam is measured. Deflection/time curves are given for samples of various plastics of different thicknesses. Log deflection/log time plots for polymethyl methacrylate and cast phenolic plastics give straight lines, which for a given material are of constant slope but differ in position according to the thickness of the specimen. C.

**Polymer Films: Electrical Current Accompanying Diffusion of Water.** C. Fischer and F. H. Muller. *Kolloid Z.*, 1942, 101, 43 (through Mark & Proskauer's *Resins, Rubbers, Plastics Abstr.*, 1943, 161). The diffusion of water in high polymers gives rise to an electric current which can be measured on a sensitive electrometer. The underpart of the frame holding the film is connected with an efficient vacuum pump (0.1 mm. Hg) which removes the diffused water vapour. The charge carried along with the water is taken up on the underside of the film by a copper gauze held in contact with the film and led to a Hoffmann electrometer with a maximum sensitivity of  $1.6 \cdot 10^{-16}$  coulomb. All other parts of the apparatus are grounded. Results for polystyrene, cellulose triacetate and polyvinyl chloride films are shown graphically. The maximum value reached by this electrical phenomenon is higher for the material with larger permeability. The smaller the permeability, the longer is the time required to attain a steady state in the diffusion. The rise of the electric current is slower the longer the time required to reach a steady state. The velocity of the appearance of this space charge must be a function of the electrical conductance of the material on the assumption that the temporary loss is accompanied by a compensating space charge in the film. C.

**High Polymer Solutions: Light Scattering.** P. M. Doty, B. H. Zimm and H. Mark. *J. Chem. Phys.*, 1944, 12, 144-145. An equation for the turbidity of a colourless binary mixture due to fluctuations in density and concentration is discussed and modified. Some preliminary measurements of the turbidity of polystyrene fractions of known osmotic molecular weight in two solvents are shown to give an expected linear relationship and the molecular weights determined from the turbidity measurements are compared with the osmotic molecular weights. C.

**Soap Solutions: Absorption of Light.** M. E. L. McBain. *J. Phys. Chem.*, 1944, 48, 89-95. Sodium oleate solutions absorb light between wave lengths of 3022 and 2594 Å. Photographic plates obtained with the mercury arc and the hydrogen-discharge tube and sodium oleate solutions of different concentrations, and graphs of the relative density of the hydrogen absorption along the  $\lambda_{2967}$  line for different concentrations of sodium oleate, show that the absorption of light may vary periodically in one series of concentrations, and irregularly in a duplicate series. Measurements of light scattering and the results of experiments in which a soap solution was placed in a small cube and the absorption measured with the cube in different positions indicated that the failure of soap solutions to obey Beer's law is due to orientation of the colloidal particles or lamellar

micelles, each solution showing different arrangements of aggregates. Other scattered observations have shown that the absorption of light by some molecules depends upon the direction in which the light passes through them. C.

**Sugars: Spectrofluorescence.** S. Judd Lewis. *J. Soc. Chem. Ind.*, 1944, 63, 157-160. When a fluorescent substance is illuminated by a spectrum, the curve of the intensity of the degraded light at successive wave lengths is an expression of the chemical nature of the substance. Suitable apparatus and technique for the study of sugars by this method are described and curves obtained for glucose, fructose, sucrose and lactose, and for mannitol medicated with glucose and with sucrose, glucose medicated with mannitol and with fructose, and sucrose medicated with mannitol and with raffinose are presented and discussed. By means of such curves it is possible to differentiate between the different sugars and also between a pure sugar and the same sugar containing a very small proportion of another sugar. The method may be applied to solids or solutions. C.

**Colour-match Filters for Tungsten Filament with Sodium Vapour Lamps.** H. G. W. Harding. *Trans. Illum. Eng. Soc.* (London), 1944, 9, 89-92. To determine the luminous intensity of a sodium vapour lamp by means of a visual photometer the radiation from the sodium lamp is generally compared with the filtered radiation from a tungsten filament lamp. A filter made from Chance OB<sub>2</sub> and OY<sub>1</sub> glasses enables the measurements to be made under colour-match and approximately energy-match conditions. Details of the construction and properties of this filter are given, and its performance is compared with that of a Zeiss glass filter. The spread in the results of six observers is about 2½ per cent. with the Chance glass filter and about 7 per cent with the Zeiss glass filter. The mean values of the readings obtained with each of the filters agree to about 2 per cent. Other filters which may be suitable for this purpose are Corning 978 with Chance OY<sub>1</sub> glasses or the combination of Wratten 23B and Wratten 57 gelatin filters. C.

**Photo-electric Photometers: Properties, Use and Maintenance.** J. S. Preston. *Trans. Illum. Eng. Soc.* (London), 1943, 8, 121-152. Problems arising in the application of emission photocells and selenium rectifier photocells to photometry are examined. The difficulties of securing a close approximation to a linear scale and to the spectral sensitivity of the standard eye, the life, stability and fatigue of photocells, temperature co-efficient, dark current, non-uniformity over the area of the sensitive surface, stray radiation, and the use of photo-electric instruments for measuring fluctuating light sources are considered. The response of the rectifier cell to oblique illumination and the size of cell best suited to any given purpose are also discussed. A number of colour correction filters proposed for use with both types of photo-cell are cited. The principles and methods of use of standard types of photometer circuits are described and critically discussed. The circuits included are the direct-reading and the integrating circuits for emission cells, and the light-meter, Campbell-Freeth, and balanced-cell circuits for rectified cells. As an example of a complete instrument, a new portable emission-cell photometer is described in which the amplifier circuit, comprising two stages of D.C. amplification, includes an electrometer tetrode, and gives a current gain of  $2 \times 10^7$  with stability adequate for measuring photocurrents down to  $2 \times 10^{-14}$  amp. to within  $\pm 5$  per cent. C.

**Portable Decade Photometer.** J. L. Nickerson. *Rev. Sci. Instruments*, 1944, 15, 69-72. Details are given of an instrument designed to meet the requirements of a practical field method for determining blood volume with the dye T-1824. In this instrument a beam passing through a cell filled with the dye-laden serum sample is compared with a similar beam which passes through a cell containing clear control serum and through filters. The matching field, instead of being continuously variable, is changed in a series of discrete and suitably related steps. This is achieved by the use of a series of coloured plastic filters which are arranged in two groups, one comprising the optical densities in the hundredths from 0.00 to 0.09 and the other the optical densities in tenths from 0.30 to 1.70. Combinations of these filters in pairs, one filter from each group, make it possible to determine optical densities from 0.30 to 1.79 in steps of 0.01, which is within the limit of intensity discrimination over most of the range. The development of the instrument is described and its advantages are pointed out. C.

**Tests with B.T.B. and B.K.B. Blowfly Dressings.** D. F. Waterhouse. *Australia: J. Council Sci. Ind. Res.*, 1942, 17, 1-15. Laboratory and field tests showed the superiority over other dressings of B.T.B. (boric acid-tar oil-bentonite) dressing. Since the recommended tar oil is not available owing to the war, other tar oils, mineral (petroleum) oils, mixtures of tar oils and mineral oils, eucalyptus and other essential oils, and mixtures containing carbon tetrachloride and ortho-dichlorobenzene were considered as substitutes, and tested for stability, powers of penetration, irritation and effect on contact toxicity. The best results were given by a mixture of ortho-dichlorobenzene, lysol and kerosene, and 20 per cent. of this was incorporated in a new dressing, B.K.B., the other constituents being boric acid (15 per cent.), bentonite (3 per cent.), Agral 2 (wetting agent), (0.5 per cent.) and water (61.5 per cent.). Tests with a number of bentonites showed the superiority of processed American clays over all other samples. W.

**Sheep Blowfly Research. (I) Survey of Maggot Collections from Live Sheep and a Note on the Trapping of Blowflies.** G. A. Hepburn. *Onderstepoort J.*, 1943, 18, 13-18. The distribution and relative importance of sheep blowflies in the Union of South Africa are surveyed. *Lucilia cuprina* is responsible for 55 per cent. of the total strikes. Trapping records at Onderstepoort are analysed, these showing the seasonal abundance of the flies. The necessity for using selective baits is stressed. W.

**Sheep Blowfly Research. (II) Suint Investigations.** M. C. A. Nolte. *Onderstepoort J.*, 1943, 18, 19-25. The possible correlation between suint composition and blowfly strike was investigated by studying the inorganic acids in the fleece. Raw wool was extracted by a modification of Rossouw's method (these *Abs.*, 1938, A 694). The following methods of isolating the organic acids were investigated: (1) the addition of ammonium sulphate to an ethyl alcoholic solution of the acids liberated from the acidified suint (Rimington and Stewart, these *Abs.*, 1932, A 352); (2) the addition of potassium carbonate to an ethyl alcoholic solution of the potassium salts of the organic acids (Lassar-Cohn, *Arbeitsmethoden f. organisch-chemische Laboratorien*, 1923); (3) extraction of the acidified suint by means of solvents, e.g. ethyl ether; (4) steam distillation of acidified suint to recover the volatile acids. Benzoic acid was identified as a decomposition product of hippuric acid, but a satisfactory separation of the organic acids present in small quantities was not achieved. Suint preparations and extracts, e.g. acid fractions, failed to attract blowflies. No correlation between suint composition and blowfly strike was demonstrated. W.

**Sheep Blowfly Research. (III) Olfactory Reactions of Blowflies.** G. A. Hepburn and M. C. A. Nolte. *Onderstepoort J.*, 1943, 18, 27-48. W.

**Sheep Blowfly Research. (IV) Field Tests with Chemically-treated Carcasses.** G. A. Hepburn and M. C. A. Nolte. *Onderstepoort J.*, 1943, 18, 49-57. W.

**Sheep Blowfly Research. (V) Carcasses as Sources of Blowflies.** G. A. Hepburn. *Onderstepoort J.*, 1943, 18, 59-72. W.

**Sheep Blowfly Research. (VI) Treatment of Myiasis.** H. O. Mönnig. *Onderstepoort J.*, 1943, 18, 75-84. The properties of an ideal dressing for the treatment of blowfly strike are enumerated and discussed. A dressing which has given good results in field tests consists of 43 per cent. alcohol (96 per cent.), 43 per cent. creosote oil (b.p. 200-240°C.), 11.25 per cent. liquid paraffin, 2.5 per cent. cresol and 0.25 per cent. sulphuric acid. An addendum states that, owing to insufficient supplies of oil, the dressing has been altered, and now has the following composition: 40 per cent. alcohol (96 per cent.), 5 per cent. second grade motor oil, 10 per cent. light fuel oil, 2.5 per cent. cresol, 0.15 per cent. sulphuric acid, 21.175 per cent. benzol and 21.175 per cent. neutral creosote oil. The efficacy of the mixture is as high as before. The effects on the various ingredients on the sheep's skin are discussed. Such mixtures are irritant to the healthy skin of most sheep, those with a relatively dry fleece being less affected than those with much yolk. W.

#### PATENT

**Bacterially-decutinized Cotton Fibre: Production.** Chemical Foundation, Inc. U.S.P.2,336,252. The claim is for a new product that readily disperses in cellulose solvents, obtained by subjecting cotton to the action of aerobic cellulose-

decomposing bacteria long enough to remove the cuticle without much destruction of the cellulose. C.

## 10—ECONOMICS

**Belgian Textile Industry: Output 1937.** Belgian Information Office. *Textile Weekly*, 1944, 34, 58, 60. Extracts from the "Belgian Handbook" show the number of operatives in various textile branches in 1937. There were 150,277 altogether, including 40,730 in cotton spinning and weaving. There were about 2 million cotton spindles and 55,000 looms. C.

**Indian Cotton Industry: Output 1942-43.** Indian Cotton Committee. *Textile Weekly*, 1944, 33, 982-4. Exports of Indian cotton for the seasons 1939 to 1943, the proportions of staple lengths above and below  $\frac{3}{8}$ -inch, and the consumption of Indian cotton by Indian mills are tabulated and discussed. Raw cotton exports have fallen from more than 3 million bales in normal years to about 150,000 bales (392 lb.) in 1943. Cloth exports have increased from about 250 million yds. to 900 million but are to be controlled at 600 million. The proportion of long and medium staples received at Indian mills has risen to 68 per cent. The quantity of mill-made cloth available for consumption in India was about 4,422 million yds. in 1937-38, but only 3,208 million yds. in 1943. Handloom production is believed to have fallen by a similar amount but Government requirements increased by about 1,000 million yds. C.

**United States Textile Exports.** United States Department of Commerce. *Textile Weekly*, 1944, 34, 74-76. Statistics of textile exports by the United States are tabulated under 31 headings for 1906, 1913, 1919 and each year from 1920 to 1939. C.

**Battle of the Fibres.** *Wool Rec.*, 1944, 65, 890-895. Quotation from an article in a recent issue of the *New England Letter* of the First National bank of Boston. W.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY, AND EDUCATION

**Air-borne Infection: Control.** O. H. Robertson. *Science*, 1943, 97, 495-502. A survey is made of evidence for aerial transmission of infection and measures are reviewed for the control of air-borne infection, including (1) means designed to prevent dispersal of infectious material into the air, e.g. isolation, masking and dust control, and (2) measures for reducing the infectivity of contaminated atmospheres, e.g. ventilation, ultra-violet irradiation, and chemical air sterilisation. Promising results obtained with ultra-violet radiation are reported and limitations of this method of sterilisation are pointed out. Studies of the air-sterilizing effects of sodium hypochlorite, various aerosols, and propylene glycol are discussed and it is pointed out that the question of the possible toxic effects from breathing atmospheres containing chemical compounds can be answered only by long-term observations on appropriate animals. C.

**Virginia Mills Institute of Textile Technology: Establishment.** *Science*, 1944, 99, 342. An Institute of Textile Technology has been established in Charlottesville, Va., by trustees representing 28 textile mills in the East (U.S.A.). Its purpose is to maintain an educational institution and to promote scientific research and processes related to the textile industry. The charter provides that none of its profits shall go to any member or individual and expressly prohibits its use of propaganda designed to influence legislation. C.

# THE JOURNAL OF THE TEXTILE INSTITUTE

## ABSTRACTS

### 1—FIBRES AND THEIR PRODUCTION

#### (B)—ANIMAL

**Sheep Husbandry in India.** R. L. Kaura. *Indian Vet. J.*, 1943, 19, 307-318.

**Genetics of the Wensleydale Breed of Sheep. III. Arithmetical Aspects of Selection.** F. W. Dry. *J. Genetics*, 1943, 45, 265-268. This paper discusses (1) numerical aspects of selection for a simple heterozygote, and (2) selection for a fancy point (blue complexion) as considered from the livestock breeding angle, with progeny testing kept in mind. W.

**Merino Sheep: Density and Development.** R. Wagner. *Merino Breeders' J.*, 1944, 6, No. 2, 11-14. A certain amount of development is necessary to maintain the standard of merino sheep. The relationship of fibre density to development is discussed in connection with practical methods of judging density. W.

**South African Merino: Future.** J. R. Bührmann. *Merino Breeders' J.*, 1944, 6, No. 2, 15-16. The pure merino is no longer an economic proposition in South Africa. The new ideal is the plain-bodied merino which can compete as a producer of both wool and mutton. In developing this type, South Africa must no longer be guided by Australian ideals. W.

**Merino Sheep: Development.** A. G. L. Murray. *Merino Breeders' J.*, 1944, 6, No. 2, 17, 19-20. Top stud rams must possess exaggerated characters to counteract Nature's tendency to reduce the sheep's wool producing capacity. Loss of productivity is slow in becoming evident, but will ultimately be the result if extremely plain-bodied rams are used. The question of neckfolds is briefly discussed, and a plea made for uniformity of the merino type in South Africa. W.

**Plain-bodied Merino: Advantages.** B. T. Harris. *Merino Breeders' J.*, 1944, 6, No. 2, 21, 23. W.

**Plain and Developed Sheep.** C. H. Gilfillan. *Merino Breeders' J.*, 1944, 6, No. 2, 23. In South Africa, as in England and Australia, type must vary according to environment. W.

#### (C)—VEGETABLE

**Cotton: Production in Ethiopia.** F. de V. Joyce. *East African Agric. J.*, 1943, Jan. et seq. (through *Empire Cotton Grow. Rev.*, 1943, 20, 95). A discussion of the future of agriculture in Ethiopia. Imports of raw cotton, yarns and fabrics before the Italian occupation were about 7,500 tons per annum. The Italians started schemes for native production, including the establishment of ginneries in five localities and a mill capable of producing over 9,000 yards of cloth per day. This mill imported most of its cotton from India, Iran, etc. Cotton has always been grown in small patches all over Ethiopia at suitable altitudes, and coarse but useful yarn and cloth are produced. A better type of handloom would help the native industry. C.

**"Tifton Station 21" Cotton.** *Mimeogr. Paper Ga Coastal Plain Exp. Sta.*, 1942, No. 15, 2 pp. (through *Plant Breed. Abstr.*, 1944, 14, 142). Tifton Station 21 is a new cotton variety which originated as an individual plant selection from Dixie Triumph. It is a vigorously growing type suited to conditions in southern Georgia. C.

**Cotton Plants: Breeding in Queensland.** R. W. Peters. *Queensland Agric. J.*, 1943, 57, 142-146 (through *Plant Breed. Abstr.*, 1944, 14, 98). The various improvements desired by Queensland cotton breeders are outlined and an

account is given of the methods of mass selection, individual plant selection and hybridization. C.

**Cotton Plant: Hybridization.** L. M. Humphrey and A. V. Tuller. *Rev. Fac. Nac. Agron.*, Colombia, 1943, 5, No. 20, 37-41 (through *Plant Breed. Abstr.*, 1944, 14, 142). The method described consists in placing portions of drinking straw, containing the unopened anther of the pollen parent, over the emasculated flower and attaching it with copper wire. No further operation is then necessary till harvest. C.

**Cotton Plant: Natural Crossing; Effect of Corn Barriers.** O. A. Pope, D. M. Simpson and E. N. Duncan. *J. Agric. Res.*, 1944, 68, 347-361. A study was conducted for two years on the effectiveness of guard plantings of corn on natural crossing in cotton, in which four conditions of guarding were included, viz., Green-leaf adjacent to red-leaf cotton surrounded by corn; and green-leaf separated from red-leaf by 3, 6 and 9 rows of corn. The amount of natural crossing was determined by planting approximately 1,500 seeds from each row of the plots of green-leaf cotton and determining the percentage of natural hybrids. The data may be interpreted simply and directly, since equal areas were planted to green- and to red-leaf cotton. The results indicate that corn barriers are effective in reducing the amount of natural crossing and that the reduction tends toward linearity for the different barrier widths used in this experiment. Despite the indicated efficiency of barriers in reducing the amount of natural crossing, the results show clearly that the barrier widths of corn used did not afford sufficient protection, under the conditions of the experiment, for the multiplication of selfed-line seed stocks. The minimum amount of natural crossing found would in a few generations of multiplication reduce the homozygosity to a point where the seed stocks would be too badly mixed for continued production. Small-block plantings of red-leaf cotton, made at distances ranging from 700 to 4,200 ft. from green-leaf cotton, established the occurrence of natural crossing at distances up to 0.8 mile. It therefore seems clear that distances of 1 mile or more will be required to provide complete isolation, under the conditions prevailing in this study. C.

**Cotton Plant: Progeny-row Breeding.** J. B. Hutchinson and H. L. Manning. *Empire J. Exp. Agric.*, 1943, 11, 140-154 (through *Plant Breed. Abstr.*, 1944, 14, 98). The breeding histories of superfine Sea Island V<sub>135</sub> and U<sub>4</sub> cottons are described. The capacity of these varieties to respond to selection appears to be a function of the genetic variance of the material. Advantages of progeny-row breeding over mass selection are considered with special reference to the problem of conserving genetic variability. It is pointed out that analysis of breeding material should be made at intervals in order to assess the progress made in the breeding projects under consideration. C.

**Ammonium Nitrate: Use as Cotton Fertilizer.** J. J. Skinner. *Com. Fertilizer*, 1944, 68, No. 2, 18-20 (through *Chem. Abstr.*, 1944, 38, 2154<sup>9</sup>). Agronomic work comparing ammonium nitrate with other nitrogen carriers is reviewed. The value of ammonium nitrate is in most cases about the equivalent to that of sodium nitrate or ammonium sulphate. C.

**Cotton Bolls and Leaves: Water Transfer.** V. A. Novikov. *C. r. Acad. Sci. U.R.S.S.*, 1941, new series, 32, No. 4, 288-290 (through *Exp. Sta. Rec.*, 1943, 88, 30). Observations are reported that indicate that during the wilting of cotton plants, water is drawn from the bolls and absorbed, in the main, by the leaves. The bolls of Egyptian types under observation had more water than American types and suffered less from dehydration. The tendency of Upland cotton to form an abscission layer in the peduncle is partly explained on the basis of a high loss of water from the bolls when the leaves need it. C.

**Cotton Plant: Physiological Wilting in the Sudan Gezira.** A. S. Boughey. *Ann. Appl. Biol.*, 1944, 31, 12-18. Cotton wilt of physiological origin appears to have been present in the Gezira area of the Anglo-Egyptian Sudan since 1924 if not previously. The results of investigations of plant growth, soil water, and atmospheric conditions show that between mid-October and mid-December three factors occur that cause water stress in the crop. At some time during this period there is marked reduction in the size of the absorbing system of the plant, correlated with maximum boll development. Greatly increased day temperatures and higher evaporation prevail, and during the whole period

available water in the soil declines. The hypothesis is put forward that when all three factors occur at the same time at their maximum intensity, permanent wilting and death of the plants result; at lesser intensities wilting is followed by recovery, but with reduction of yield. Experiments are described that support this view. A return to the earlier sowing date formerly favoured locally should lead to considerably increased losses. C.

**Cotton Plant Diseases: Investigation in Texas.** W. N. Ezekiel and others. *Texas Sta. Rept.*, 1941, pp. 64-73 . . . 181-182 (through *Exp. Sta. Rec.*, 1943, 88, 59-60). A number of progress reports are given on problems connected with root-rot, wilt, angular leaf spot and other diseases. C.

**Cotton Plant Diseases: Occurrence in Uruguay.** A. de W. Berton. *Agric. Com. Ind., Asunción*, 1941, i, 57-59 (through *Rev. Appl. Mycol.*, 1944, 23, 176). The most serious disease of cotton in Uruguay is anthracnose (*Glomerella gossypii*). Other pathogens of the crop include *Bacterium* [*Xanthomonas*] *malvacearum*, wilt [*Fusarium*] [*?vasinfectum*], and the leaf spots caused by *Cercospora* [*?gossypina*] and *Ramularia* [*?areola*]. C.

**Jassid-resistant Cotton Varieties: Breeding.** S. Marriott. *Queensland Agric. J.* 1943, 57, 204-206 (through *Plant Breed. Abstr.*, 1944, 14, 99). In breeding for resistance to jassid attack, individual and mass selection, and hybridization were tried. Some correlation was found between hairiness and resistance, though not all hairy plants were resistant, and, under certain conditions, even the normally susceptible glabrous plants withstood attack. From mass selection, the rather heterogeneous strain known as 41J has been produced; this does not show more than a 20 per cent. increase in jassid resistance over the original non-selected strain. From individual selection methods the very uniform Miller strain 111-26 has been derived. It is of excellent quality, and  $\frac{15}{16}$ -in. staple length. It bears only a medium sized boll, however, and produces a rather leafy type of plant. Other selections from Miller also show promise. Hybridizing imported resistant types, such as the South African U4, that are useless under Queensland conditions, with some of the Queensland cottons such as Miller, and subsequently back-crossing for several generations to Miller, has produced promising lines. Their production has not yet reached a commercial scale. C.

**Co-operative Cotton Gin Associations: Organisation and Operation in New Mexico.** R. P. Callaway. *New Mexico Sta. Bul.*, No. 293, 1942, 35 pages. (through *Exp. Sta. Rec.*, 1943, 88, 120). An analysis of the financial reports and records of co-operative cotton gin associations for the seasons 1938-39 to 1940-41. In the last season there were 15 such associations in New Mexico, doing nearly 60 per cent. of all the ginning. The expenses averaged \$3.21 per 500-lb. bale. Nearly 40 per cent. of the gross income came from sales of cottonseed, 23 per cent. from sales of baled cotton and 18 per cent. from ginning and sterilization. Members received an average dividend of \$1.99 per bale. C.

**American Cotton: Marketing in Louisiana.** H. W. Little and R. A. Ballinger. *Louisiana Sta. Bul.*, No. 345, 1942, 27 pages (through *Exp. Sta. Rec.*, 1943, 88, 121). An analysis of cotton marketing practices in eight of the northern and central markets of Louisiana. About 30 per cent. of the producers had no knowledge of the quality of their cotton when they sold it and another 25 per cent. only knew what the buyer told them about the grade and staple. Nearly half of the producers knew something of the current spot and futures prices, but very few knew what were the premiums and discounts for grade and staple. Nearly half of the buyers were independent, more than 40 per cent. were salaried men, and about 10 per cent. were buying on commission. Most of the buyers made some attempt to determine grade and staple, but many of them appeared to do so very roughly and few had access to the full range of official standards for grade and staple. C.

**American Cotton Farmers: Financing.** W. S. Rowan and B. H. Luebke. *Tennessee Sta., Agric. Econ. and Rural Sociol. Dept. Monographs*, No. 136 and 137 (through *Exp. Sta. Rec.*, 1943, 88, 120). The authors analyse the use of mortgage and loan forms of credit by 51 farmers in a one-crop (cotton) system of agriculture in Hardeman County, Tennessee. Nearly half the farms had less than \$100 of debt. Land mortgages to buy the farms were the principal item.

Commercial banks and the Federal land bank each provided nearly one-third of the money. C.

**Mallow Fibres: Isolation.** A. C. Batista. *Rev. brasil. quim.* (São Paulo), 1943, 16, 340-346 (through *Chem. Abstr.*, 1944, 38, 2211<sup>7</sup>). Methods of preparing textile fibres suitable for spinning from the stalks of the tall mallow, *Pavonia varians*, are discussed, with special regard to various methods of retting for removal of pectinous substances. The fibre is fine and soft and dyes well. C.

**Cotton Bale: Sampling.** J. S. Jenkins. *Textile World*, 1944, 94, No. 5, 150-154. The writer criticises Mitchem's suggestion for the official sampling of cotton and points out that (1) considerable variations might be found in the judgments of grade and staple by different licensed classers, (2) spinning value cannot always be expressed in terms of grade and staple, and (3) there are in practice a great variety of private understandings between spinners and brokers as to the characters required in their cotton. C.

#### (D)—ARTIFICIAL

**Cellulose Pulps: Preparation from Lignite.** F. Reiff and A. W. Sohn. *Papier-Fabr.-Wochbl. Papierfabr.*, 1943, No. 3, 83-87 (through *Chem. Abstr.*, 1944, 38, 2200<sup>3</sup>). Various samples of lignite showed wide fluctuations in cellulose content and degree of polymerisation (D.P.). Usually the hemicellulose content was very low, and the samples consisted largely of cellulose, lignin and mineral matter. An unusual lignite contained 42 per cent. cellulose, D.P. 800. This in the form of small chips was given a chlorite-hypochlorite treatment similar to that used in wood delignification. Based on the weight of lignite, the sodium chlorite consumption was 100-135 per cent. The surface reaction was very rapid, but penetration into the chips was relatively slow, unless defibering was resorted to, in which case the chlorite consumption was also lowered. Pulp yields were approximately equal to the cellulose content (D.P. 800). The high degree of brightness of the pulp made further bleaching unnecessary. The pulp contained 87 per cent.  $\alpha$ -cellulose, 3.9 per cent. wood gum, 1.9 per cent. material that yielded furfural, and 13.1 per cent. alkali-soluble matter. A sulphate digestion of the same lignite yielded 24 per cent. of a pulp (D.P. 470),  $\alpha$ -cellulose 93.1 per cent., "wood gum" 2.8 per cent., furfural-yielding products 1.9 per cent., and alkali-soluble 7.1 per cent. Chlorite treatment also gave a stronger pulp than did the sulphate cook. Folding endurance was zero for the sulphate pulp and 2050 double folds for the chlorite pulp. Other lignites invariably gave lower pulp yields with less-satisfactory pulp qualities after chlorite treatment. Even within the same lignin deposit, samples showed wide variation in cellulose content and D.P., and this lack of uniformity makes effective technological utilisation impossible. Lignite cannot be considered a satisfactory raw material for the pulp mill. Photo-micrographs show fibre characteristics of lignite pulps of varied D.P.; defibrillation occurs and spirals formed in this way are insoluble in cuprammonium. C.

**Pulp for Viscose: Manufacture in Finland.** W. F. Meleshkin. *Bumazhnaya Prom.*, 1940, 18, No. 12, 8-16 (through *Chem. Zentr.*, 1941, ii, 1231 and *Chem. Abstr.*, 1944, 38, 2202<sup>3</sup>). The process followed in the Keksholm pulp mill employs acid of constant composition and bleaching in three phases, which gives better control of the viscosity of the pulp. The ash content is reduced and colour improved by repeated treatments with sulphur dioxide and water. C.

**Straw Pulp: Production.** J. Eggert. *Papier-Fabr., Wochbl. Papierfabr.*, 1943, No. 3, 87-99 (through *Chem. Abstr.*, 1944, 38, 2200<sup>3</sup>). The anatomy of rye, wheat, bamboo and other rapidly growing plants is described (20 photomicrographs) and general methods of pulping are reviewed. Modern methods involve heating the clean straw with acid at 120° C. (to hydrolyse non-cellulosic carbohydrates), neutralisation, treatment with alkali (dilute at 120-130° C., or concentrated in the cold), washing, chlorination, further treatment with mild alkali, and bleaching. C.

**Rayon Spinning Nozzle Alloys.** H. Nisimura. *Japan Nickel Rev.*, 1941, 9, 4-16 (through *Chem. Zentr.*, 1941, ii, 2893 and *Chem. Abstr.*, 1944, 38, 2200<sup>1</sup>). Tantalum and zirconium are suitable for rayon spinning nozzles; the resistance to wear of tantalum can be increased by oxidation. Gold is too soft, but alloys with platinum or gold can be used. The gold-palladium products are mostly pure solid-solution alloys, which cannot be heat-hardened, but they can be

hardened by the addition of other components. The following suitable alloys are discussed: gold-platinum (20%)–nickel (1%); gold-platinum (10%)–chromium (1%); gold–silver (5%)–aluminium (0.3%)–nickel (3.1%) and “Cohky” metal which contains gold, platinum, nickel, and another component that is not revealed. Many phase diagrams are shown and data are given on the physical and technical properties of alloys and pure metals. C.

**Rayon Filaments and Fabrics: Production.** E. Dersucher. *Ind. textile*, 1941, 57, 250; 58, 292, 330–331, 421–422 (through *Chem. Zentr.*, 1941, ii, 2757 and *Chem. Abstr.*, 1944, 38, 2199<sup>4</sup>). The composition of primary spinning baths and of the after-treatment baths is discussed. The spinning nozzles become clogged only rarely if the amounts of zinc sulphate and sulphuric acid in the primary baths are lowered and if larger amounts of magnesium sulphate are used. However, zinc sulphate cannot be replaced completely by magnesium sulphate. The impermeability and crease-proofing of natural and artificial cellulose fabrics can be improved by treatment with copper sulphate and caustic alkalis and by stretching. Additional data are given on the Carlier process of manufacturing synthetic wool, the manufacture of viscose threads with hollow spaces arranged irregularly throughout the thread, and an apparatus for the manufacture of staple fibre. C.

#### PATENTS

**Rayon Spinning Apparatus.** American Viscose Corporation. B.P.562,271 of 6/11/1942:26/6/1944 (Conv. 11/12/1941). Apparatus for the production of rayon filaments comprises a centrifugal bucket and means for draining solutions or suspensions from the immediate surroundings of the bucket into a common drainage channel leading to a discharge system, means for intermittently spraying the exterior of the bucket during operation for the purpose of removing crystals formed thereon, and means for automatically diverting the effluent from the drainage channel during spraying to a separate discharge system. The drainage system may comprise a double-chambered box for receiving the drainings, a tiltable trough for deflecting the drainings alternately into the two chambers of the box, means for tilting the trough, and means for simultaneously and intermittently operating the tilting means and the spraying means. C.

**Hydrophilic Polyamide Filaments: Production.** Imperial Chemical Industries Ltd. (E. I. Du Pont de Nemours & Co.). B.P.562,370 of 14/5/1942:29/6/1944. Polyamides having enhanced water-absorption characteristics and improved physical properties are obtained by heating in the molten state at amide-forming temperatures a mixture of at least two pre-formed synthetic linear polyamides, one at least being soluble in water and one at least insoluble, until a homogeneous melt is obtained. The changes in characteristics and properties are made more pronounced by treating the solidified melt, in whatever form desired, e.g. filaments or films, with a swelling agent, namely, water, a short-chain aliphatic alcohol, e.g. methanol, or a mixture of these. Usually, the melt-blended polyamide is formed into a structure and orientated, as by cold-drawing or cold-rolling, prior to treating with the swelling agent, and ordinarily it is permitted to shrink more or less freely during the treatment. C.

**Rayon Staple Cutter.** American Viscose Corporation. B.P.562,519 of 28/1/1943:5/7/1944 (Conv. 29/1/1942). Apparatus for cutting filamentary material at intervals into discontinuous fibres of various lengths comprises a rotating member for feeding the material to the knife and means for automatically and continually varying the speed of rotation of the member. The rotating member may feed the material radially outwards by centrifugal force and the cutting means may be adjacent to its periphery. C.

**Filament Crimping Apparatus.** American Viscose Corporation. B.P.562,520 of 29/1/1943:5/7/1944 (Conv. 31/1/1942). Apparatus for crimping filamentary material comprises a pair of projecting elements with a groove between them, a number of independently operable members, means for feeding the material transversely of the elements and groove, means for moving one of the members into clamping engagement with the material against one of the elements and means for moving another of the members into the groove

for crimping the material. The projecting elements and groove may form part of a drum having a transversely grooved surface. C.

**Cellulose Higher Fatty Acid Esters: Purification.** J. W. Fisher. B.P.562,691 of 14/12/1942:12/7/1944. Higher fatty acid esters of cellulose, and especially mixed cellulose esters of higher and lower fatty acids, which are contaminated with free higher fatty acid, are purified by extracting the acid from the ester by means of an aqueous solution of a lower aliphatic alcohol which at ordinary temperatures is completely miscible with water, the concentration of the aqueous alcohol being such that, at the temperature employed for the extraction, the cellulose ester is not substantially softened thereby. By this means it is possible to effect a substantially complete separation of the cellulose ester and the higher fatty acid, so that a cellulose ester free from uncombined acid, and a higher fatty acid free from cellulosic impurities, are obtained. The extraction is preferably carried out with aqueous ethyl alcohol at concentrations of about 50-85 per cent. and temperatures up to about 80° C. C.

**Rayon Spinning Machine.** American Viscose Corporation. B.P.562,860 of 2/11/1942:19/7/1944 (Conv. 25/10/1941). In a spinning machine for producing artificial yarns or filaments comprising a number of spinning tubes each having at one end a spinneret and at the other end an orifice through which the formed yarn or filament is withdrawn, and an inlet and outlet for a gaseous medium which is passed through the spinning tube, there is provided a duct for conveying the gaseous medium and means for supplying to the inlet of each of the spinning tubes gaseous medium from two portions of the duct, so that all the spinning tubes are supplied with gaseous medium at substantially the same temperature. C.

**Polyamide Solutions: Preparation.** E. I. Du Pont de Nemours & Co. B.P. 563,078 of 17/9/1941:28/7/1944 (Conv. 24/10/1940). Solutions of synthetic linear polyamides are prepared by dissolving the polyamides in solutions of inorganic salts in lower aliphatic alcohols. The chlorides, bromides and nitrates of lithium, calcium and zinc are particularly suitable salts. In most cases polyamide solutions of high solids content and good stability can be conveniently prepared by agitating the polyamide with the solvent mixture at room temperature or at slightly higher temperatures. In some cases, however, it is advantageous to agitate the polyamide with the solvent mixture at the boiling point of the latter, under a reflux condenser. A given solvent medium may have a swelling action on a given polyamide at room temperature, forming a rigid gel which, however, can usually be dispersed by heating. When the solution is cooled, the time interval before a gel is formed again varies with the nature of the polyamide, the solvent medium, and plasticizers or other materials present. In some cases the super-cooled solutions can be handled at room temperature for several days before gel formation occurs. It is sometimes of advantage to use an unstable solution in the formation of films, fibres, coatings, etc. For the production of dispersible particles of the polyamide, alcohol-salt-polyamide solutions are diluted with a non-solvent for the polyamide, e.g. the alcohol used in forming the solution, thus causing precipitation of the polyamide. C.

**Fibre Liquid Treatment Apparatus.** Celanese Corporation of America. U.S.P. 2,337,068. Apparatus for treating fibre with a liquid consists of an open-end trough, a perforated apron for carrying the fibre through the liquid, and transverse rollers at intervals along the trough for enclosing the liquid. C.

**Varying Denier Rayon Spinning Apparatus.** Celanese Corporation of America. U.S.P.2,337,664. The claim is for a device, employing a cam-actuated piston in a pressure cylinder, for applying a quick increase in pressure on the solution being fed to the spinneret, followed by a slow release, a period of constant pressure and then another quick increase, and so on. C.

**Crimped Filament Spinning Apparatus.** G. Bugge (Germany; vested in the U.S. Alien Property Custodian). U.S.P.2,337,969. Apparatus for producing wool-like filaments comprises a pair of opposed rollers having mating grooves of undulating form, and means for feeding spinning solution to the nip of the rollers. C.

## 2—CONVERSION OF FIBRES INTO FINISHED YARNS

### (A)—PREPARATORY PROCESSES

**Cotton Waste: Oiling.** V. V. Laikov. *Khlopchatobumazh. Prom.*, 1940, 10, No. 11-12, 20-22 (through *Chem. Zentr.*, 1941, ii, 2511 and *Chem. Abstr.*, 1944, 38, 2215<sup>3</sup>). Cotton waste mixtures are oiled to facilitate spinning. A mixture of oleic acid, machine oil, soda or ammonium hydroxide, and water is used. Various oil mixtures were tested on the same waste mixture and the tensile strength of the yarn during spinning was determined. Parallel tests were made with "Verol" alone and in mixtures with the above chemicals. Verol essentially improved the quality of the yarn and was cheaper (its composition is not disclosed). C.

**Drawing: Maintaining Balance of Supply and Demand.** *Wool Rec.*, 1944, 66, 64-68. Even a slight lack of balance between the different stages in drawing causes production to be limited to that of the slowest machines and the slowest operatives. Suggestions are made for regulating supply and demand between machine and machine, these including alterations to spindle speeds, number of doublings and draft. W.

### (B)—SPINNING AND DOUBLING

**Drafting Roller Coverings: Properties.** F. Wooding. *Textile Weekly*, 1944, 34, 148-150. The writer describes the qualities required in a drafting roller covering and favours composition cork coverings. C.

**Roving Frame Production Tables: Application.** *Textile World*, 1944, 94, No. 5, 71-78. A set of eight tables is provided from which to derive the production of roving frames under common conditions. They are based on 10-hours run, 4- and 5-roller high draft; Tables 1-4 are for  $1\frac{1}{2}$ -inch and 5-8 for  $1\frac{3}{8}$ -inch front rollers, and for each of these rollers there are tables for  $10 \times 5$ ,  $9 \times 4\frac{1}{2}$ ,  $8 \times 4$ , and  $8 \times 3\frac{3}{8}$  bobbins. The columns are headed (1) hank roving, (2) twists per inch, (3) front roller revolutions per minute, (4) time from one doffing to the next, (5) time to produce 1 lb. of sliver, (6) and (7) production at 100 per cent. efficiency in hanks and pounds, and (8)-(15) actual production after allowing 8, 9, 10 . . . . 15 minutes for each doffing. Another table gives average estimates of the percentage of time lost in piecing, week-end cleaning, etc., on frames of 90, 100, 110 . . . . 170 spindles, and the production figures derived from the main tables are intended to be corrected for the "percent. incidental stops" (other than for doffing) read from the appropriate row in the small table. Several examples are worked out to show the application of the tables. C.

**Spring-controlled Flyer Presser Arm.** T. L. McGovern (Providence, R.I.). *Textile World*, 1944, 94, No. 5, 130. Sketches are given of a presser arm which is shaped to engage one arm of the flyer and is held at the top by a collar inside which is a flat spring. The centrifugal force that tends to urge the presser foot outwards is countered by the spring so that the foot exerts uniform pressure on the roving bobbin. More compact and even bobbins are claimed. The springs can be varied so as to secure different bobbin densities. C.

**Twist: Influence in Spinning Worsted Yarn on the Bradford System.** "K.M.G.," *Wool Rec.*, 1944, 65, 970, 973. Variation in quality of tops must be provided for in twisting in drawing. If spun straight from the roving frames, more twist is needed than if the rovings are to be put into stock. The amount of twist in spinning is influenced by the system of spinning, the quality and blend of wool and other fibres, and the ultimate purpose of the yarn. Standard twists for each count are only possible in theory, because twist is affected by wool fineness and length; in the case of two-fold yarns various formulae have been suggested, but most are correct only over a limited range of counts. The best general rule is to use the minimum twist consistent with a good spin, taking into account future requirements, e.g. twisting. Coloured yarns require more twist than white ones, and special twists may be needed for special effects. Alterations in twist over small limits appear to make little difference to the two-fold strength of the yarn; the strength is increased by increase in folding twist. W.

### (D)—YARNS AND CORDS

**Rayon Tyre Cord: Production.** Industrial Rayon Corporation. *Textile World*, 1944, 94, No. 5, 79. The Industrial Rayon Corporation has planned two fac-

tories each for producing about 20 million lb. of rayon tyre cord annually. The initial 1100-denier yarn is spun, stretched, washed, treated, dried, given a preliminary twist and wound on bobbins by a continuous process. Two threads are then wound parallel on a twist spool and then cable-twisted into the finished "Tyron" cord. This is beamed from creels into 1000-lb. beams, loosely woven with a fine weft, and the cord fabric is delivered to tyre manufacturers in rolls up to 1000 yards.

C.

#### PATENTS

**Cottonized Flax Carding Machine.** Aktiebolaget Svenska Textilverken (Genevad, Sweden). B.P.562,253 of 22/12/1942:23/6/1944 (Conv. 27/12/1941). A carding machine for cottonized flax provided with one or more lickers-in, a main cylinder and a doffer, comprises in combination the following working members arranged between the lickers-in and the doffer around the main cylinder in the direction of rotation of the same: an adhesion plate for providing a uniform transfer of the material to the main cylinder, one or more rollers and clearers, stationary or movable flat carding means and a device for lifting the material outwardly on the main cylinder. The machine can also be used for the treatment of cotton or rayon staple fibre.

C.

**Fibrous and Comminuted Material Mixing Apparatus.** British Cotton Industry Research Association and T. C. Williams. B.P.562,308 of 22/9/1942:27/6/1944. For the intimate and uniform admixture of fibrous materials and comminuted materials and the production of fleeces, wads, laps, bands or slivers, means for opening and collecting fibrous material of the type described in B.P.404,686, 423,321 or 483,653 are supplemented by means for introducing into the air stream at a controlled rate the comminuted material. The latter may be fed at any or all of a number of places, first, at the entrance to the dirt chamber below the feed roller; secondly, into the space between the upper surface of the beater and the beater cover whence it is carried to where the beater strikes the fibrous material and passes with this into the dirt chamber; thirdly, on to the feed of fibrous material, the comminuted material being dropped on to laps of fibrous material as they lie on the feed lattice so that the comminuted material is "sandwiched" between the laps as they pass between the feed roller and the whole mass is disintegrated by the action of the beater; fourthly and fifthly, at two places which are less favourable for uniform admixture, i.e. respectively through an aperture in the top plate of the region between the beater and collecting means or where the air stream emerges into the region between the beater and the collecting means. To obtain any desired relative proportion of fibrous and comminuted materials, use is made of means for feeding the latter which may be regulated in relation to the feed of the former. The preferred means of regulating the feed of comminuted material is a hopper having an oscillating side, the frequency and amplitude of whose oscillations are capable of regulation.

C.

**Yarn Doubling Apparatus.** British Celanese Ltd. B.P.562,682 of 17/9/1942:12/7/1944 (Conv. 19/9/1941). A method of doubling together yarns of different twist/shrinkage characteristics comprises feeding the yarns at different rates to the feed roll of a twisting and doubling spindle and doubling the yarns with such a degree of twist that the components in the resulting yarn are substantially equal in length. The yarn that is fed at the lower rate may be drawn from the source of supply by the feed roll of the doubling machine, and the feeding of this yarn may be utilised to feed the other yarn or yarns from the source of supply at the higher rate. For carrying out this method an attachment may be mounted between the feed roll of the doubling machine and the source of supply, comprising drawing means driven by the engagement of the yarn that is to be fed at the lower speed, and serving to feed the other yarn or yarns from the source of supply at a greater speed, so that the other yarn or yarns reach the feed roll under little or no tension and consequently play little or no part in driving the drawing means. As the means for drawing the yarns from the source of supply, wheels or rollers having portions that are of different diameters may conveniently be employed.

C.

**Spinning and Twisting Frame Spindle and Sleeve.** W. W. Triggs (Spindel-Motorën u. Maschinenfabrik A.-G. vormals Weber & Co., Uster, Switzerland). B.P.562,849 of 10/7/1942:19/7/1944. A spindle and sleeve system for spinning and twisting frames is characterised in that the sleeve is made of a metallic

tube which at one end is supported on a crowned or curved shoulder of the spindle base and at the other end on a similar shoulder of the spindle head, and that the sleeve is allowed a slight axial play between the base and head in order to permit the spindle shaft to deflect resiliently without being hindered by the sleeve. The shoulders which serve as bearings for the sleeve may be provided with annular grooves, each of which contains an elastic ring which is slightly pressed against the inner surface of the sleeve. The conical tube serving as the spindle sleeve may be provided with a number of longitudinally disposed grooves which deepen toward the narrower end of the tube and which serve as stiffening ribs for the latter. C.

**Carding Engine Belt-shifter Mechanism.** J. & P. Coats Ltd. and I. P. Coats. B.P.563,056 of 11/2/1943:27/7/1944. A belt-shifter fork-member includes a limb in the form of a deep blade and another limb in the form of a rod, the limbs being connected together by a bridge component, the fork-member being pivotally mounted at its bridge end on an actuating member so that the fork-member may be swung away from and towards the associated belt pulleys, when required. The blade limb is very thin in the direction of belt-shifting movement of the fork-member and is deep in the direction perpendicular to the direction of belt-shifting movement, so as to form a guard plate of which one edge lies close to the pulleys and which is engageable with the outer edge of the belt. The fork-member is particularly applicable to a carding engine having a driving shaft carrying a loose pulley and a fast pulley each provided or associated with at least one V-grooved auxiliary pulley. The auxiliary pulleys are adapted to be used for rope drives in stripping and grinding operations. C.

**Narrow Ring Frame.** Saco-Lowell Shops. B.P.563,079 of 17/3/1942:28/7/1944 (Conv. 16/7/1941). In a two-sided ring frame, the two rows of roving bobbins are respectively mounted closely adjacent to, and directly over the two sets of drawing rollers, the back rollers of each set being set closely together and separated by a space narrower than the over-all lateral width of either set of rollers and too narrow to accommodate a creel. This arrangement permits a reduction in the width of spinning frames. C.

### 3—CONVERSION OF YARNS INTO FABRICS

#### (A)—PREPARATORY PROCESSES

**Nylon Yarn: Winding, Sizing and Weaving.** E. I. Du Pont de Nemours & Co. *Textile Manufacturer*, 1944, 70, 263-4. Practical hints are given on the preparation for weaving, and the weaving, of nylon yarns under the headings (1) winding tension, (2) knot tying, (3) oiling, (4) tinting for identification, (5) single-end sizing, (6) warping and sizing, (7) pirn winding, (8) weaving, and (9) suppression of "static" charges. C.

**Winding Machines: Efficiency, Lubrication and Maintenance.** R. F. Langford. *Textile World*, 1944, 94, No. 4, 110-111. The following particulars are tabulated. I—Production and assignment; for No. 50 "Universal," No. 90 "Universal" pirn, and No. 30 "Foster" winders. The columns are headed type of yarn, spindles per operative, average machine efficiency, production per spindle per 1, 8 and 24 hr. at 100 per cent. and at the average efficiency, and the type of package. II—Lubricating schedules for the same winders, giving the lubricating point, the frequency of lubrication, the type and viscosity of the lubricant, and the amount used. III—Maintenance schedules, with details of routine inspection, cleaning and overhaul. C.

#### (B)—SIZING

**Linseed Oil Size: Decomposition.** H. J. Henk. *Kunstseide u. Zellwolle*, 1942, 24, 304-306 (through *Chem. Zentr.*, 1942, ii, 2101 and *Chem. Abstr.*, 1944, 38, 2215<sup>4</sup>). A description is given of the processes of autoxidation, oxidative degradation of textiles, and the action of catalysts and anti-oxidants during drying and film formation. C.

**Nylon Yarn: Single-end Sizing.** R. C. Pillsbury. *Textile World*, 1944, 94, No. 4, 118-120. Full particulars are given of the sizing and coning of nylon yarn for knitting. The yarn is supplied on 1-lb. packages or re-wound on 4- or 8-oz. spools. The sizing machine imposes a positively-controlled tension before the yarn reaches the sizing roller; the tension is 3-14 gms., according to the denier of the yarn. The arc of contact with the sizing roller is set by gauge to

5°. The size is a solution of polyvinyl alcohol (8.0 per cent.), boric acid (1.6) and water (90.4); this is kept in circulation and its viscosity checked every 4 hours and maintained at 115-125 Saybolt seconds. The sizing room is maintained at  $84 \pm 2^\circ$  F. and  $50 \pm 2$  per cent. R.H.; if the limits are exceeded trouble from static charges may be expected. The sized yarn is wound on Bakelite drums, 6 ins. diameter; 8 oz. is a convenient weight. The spindle speed is 1,250 r.p.m., equivalent to a yarn speed of 685 yds. per min. on the bare cylinder, 700 yds. at  $6\frac{5}{8}$  ins. (=8 oz. of yarn) or 733 yds. at 7 ins. (=1 lb. of yarn). The sizing roller is driven by reduction gear over the range 4.9-26.5 r.p.m., and turns in the direction of yarn travel. About 4 per cent. of dry size is commonly added (=40 per cent. of actual size picked up). The sized tubes are steamed to set the twist and left for 12 to 24 hours in the sizing room and a further 12 hours in the coning room before further processing. Coning tension should be very little more than that required to pull the yarn off the sized tube; this and the applied tension together should be about 6 gms. per end at the start, and 4 gms. at the end of the cone. Pineapple cones of 8-12 oz. are usual, with  $3\frac{1}{4}$  winds across the package. Coning speed may be 1,250 r.p.m. or 285 yd. per min. at the start of a  $3\frac{1}{4}$  in. cone. The room should be at  $76^\circ$  F. and 72 per cent. R.H. C.

**Nylon Yarn: Single-end Sizing.** *Textile Manufacturer*, 1944, 70, 307. An illustration is given of a "flash defect" that may be found in fully-fashioned nylon stockings if there are short-period irregularities of twist in the yarn. The defect takes the form of skewed stitches which show up as streaks and furrows in the dyed stocking. Recommendations are made for the winding tension and the sizing of the yarn before crêpe twisting, coning and oiling so as to avoid the defect. Du Pont's size for nylon is mainly a partly saponified polyvinyl acetate, with boric acid and polyethyleneglycol. Two sizing, twisting and oiling experiments are reported in which the range of twists per 2½-inch lengths of yarn were 58-87 and 71-82, respectively (averages 75). Fully-fashioned stockings made from these yarns were free from the above defect. C.

#### (C)—WEAVING

**Automatic Loom Shed: Staffing.** H. de G. Gaudin. *Textile Manufacturer*, 1944, 70, 284. The writer gives an estimate of the number of workers required for a shed with 180 automatic rayon looms on one shift and on two shifts. The total for two shifts is 56 persons, whereas Lowcock gave the figure 102 for 175 looms, or very little less than the number that would be required on non-automatic looms. Lowcock's article is strongly criticised. C.

**Wire Weaving Looms.** Robert Hall & Sons (Bury) Ltd. *Textile Manufacturer*, 1944, 70, 257-9, 269. A general account is given of the weaving of wire and mono-filaments, followed by details of shuttle looms suitable for (1) light wire cloths of 8-120 meshes per inch and wire of 28s-42s gauge, (2) medium cloths of 8-80 meshes and 25s-38s gauge, and (3) heavy cloths up to 26s gauge. C.

**Plain Fabrics: Obtaining "Cover" in Weaving.** *Indian Textile J.*, 1944, 54, 228-229. Practical hints are given on loom settings to secure good "cover" in weaving plain fabrics. C.

**Shuttle-changing: Influence on Weaving Efficiency.** T. Oliver. *Wool Rec.*, 1944, 65, 880. Reference is made to a previous article (these *Abs.*, 1944, A337) and a simple mathematical analysis given of the problem of weaving efficiency in relation to count of yarn and shuttle-changing. W.

#### (D)—KNITTING

**Knitting Machine Needles: Straightening.** J. C. Cobert. *Cotton (U.S.)*, 1943, 107, No. 11, 134-5. A simple and quick plan is given for teaching the operative how to see and correct needle defects, and a needle inspector's report form is reproduced. C.

**Knitting Yarns: Selection.** C. W. Bendigo. *Textile World*, 1944, 94, No. 4, 81-88. A series of tables are provided to show the sizes of rayon (and pre-war nylon), cotton, worsted and woollen yarns suitable for the various parts of (1) fully-fashioned hosiery, (2) women's seamless hosiery, (3) men's half hose, (4) underwear, and (5) outerwear. The tables are divided into sections, e.g. leg, welt, reinforced heel and sole and toe, and in each section the columns give the

machine gauges, minimum, maximum and normal yarn counts, and folding twists. C.

**Fully-fashioned Hosiery Machines: Development.** P. Kroener. *Textile World*, 1944, 94, No. 5, 97. The writer discusses the limitations to gauge and speed in fully-fashioned knitting machines and forecasts a post-war machine in 30 sections, gauge 51 and 14-inch needle bars to cover the range of 15- to 40-den. nylon or 2- to 7-thread silk. C.

#### (G)—FABRICS

**Nylon Corset Cloths: Development.** Katherine Mackenzie. *Textile Manufacturer*, 1944, 70, 265 (from *Canadian Textile Journal*). The writer refers to work at the Ontario Research Foundation by the Nylon Division of Canadian Industries Ltd. on the development of nylon yarns for other purposes than stockings. A marquisette for corsets and underwear shows much promise. C.

**U.S. Army Wool Socks.** *Text. World*, 1944, 94, No. 3, 93, 152. Manufacturing data are given for spinning merino yarn for U.S. army socks (light-weight wool and cushion-sole) on the worsted and cotton systems. Lowering the grade of wool used has reduced shrinkage by one-third (see these *Abs.*, 1944, A146). W.

#### PATENTS

**Knitting Machine Fabric Take-up Mechanism.** Hemphill Co. (U.S.A.) and R. C. Southworth. B.P.562,247 of 21/10/1942:23/6/1944 (Conv. 23/10/1941). Fabric take-up mechanism for knitting machines comprises opposed rollers mounted so as to be capable of swinging or moving apart to accommodate different thicknesses of fabric passing between them, yielding means for resiliently urging the rollers towards one another, and a pawl and ratchet device for driving each roller independently at any position it may take up. C.

**Wear-resistant Canvas Hosepipe.** Lewis & Taylor Ltd. and N. Lawson. B.P. 562,326 of 1/2/1943:27/6/1944. Seamless woven canvas hosepipe is composed of warp and weft threads with some of the warp threads standing out or lying beyond the remaining surface of the hosepipe for the purpose of providing a wear-resisting face. The wear-resisting threads are introduced parallel with the ordinary warp threads and fed into the loom at a higher rate than the ordinary warp threads. They may be of the same or different material from the ordinary warp threads. C.

**Constant Tension Winding Machine.** Slack & Parr Ltd. and H. Slack. B.P. 562,622 of 12/1/1943:10/7/1944. In an arrangement for keeping the pull on the thread or other material being wound substantially constant as the bobbin fills up, the winding bobbin is driven by means comprising a set of permanent magnets, a prime mover for rotating them to produce a rotating magnetic field, and an associated rotor coupled to the bobbin, the rotor being of squirrel cage construction, but modified so as to be capable of developing a large slip. C.

**Two-piece Stocking.** E. Dickinson. B.P.562,926 of 19/2/1943:21/7/1944. A stocking is made in one portion that comprises the leg and a part of the foot, and a second portion forming the toe and part of the foot. In use one portion overlaps the other and the two may be fastened together with suitable material. The length of the overlap is such that any creep of the two portions does not allow them to separate. C.

**Glass Fibre Wicks.** H. H. Goldstaub. B.P.563,050 of 5/1/1943:27/7/1944. A wick is composed wholly or mainly of glass fibres and has an end or edge temporarily or permanently sealed by the application of heat to the fibres accompanied either by tension or some compacting or shaping process to facilitate assembly in a wick holder or use therein or for both purposes. A method of compacting and tapering the edge or end of a glass-fibre thread or fabric comprises applying heat at an intermediate region or point while stretched until severance occurs at the heated region. If desired, cotton fibres or the like may be incorporated with the glass fibres, but it is preferred that the bulk of the wick shall comprise glass fibres. C.

**Mesh Fabric Knitting Machine.** Harry Harris (Tuckerton, N.J.). U.S.P. 2,337,102. The claim is for a machine with a straight series of needles, cam-actuated narrowing mechanism supporting a picot comb that can shift endwise along the needles to transfer loops between certain spaced needles (a) and

adjacent needles (*b*) incidental to the dipping, lifting and dipping of the narrowing mechanism in loop transferring operation, and a pair of cams for shifting the picot comb as required either between the first and second dips as loops are transferred from needles (*a*) to needles (*b*) or before the first dip as loops are transferred from (*b*) to (*a*). C.

**Warping Machine Compacting Device.** Davis & Furber Machine Co. U.S.P. 2,337,129. A device for compressing warp as it is being wound on a beam comprises a base carrying a main shaft that is fixed parallel to the beam, upstanding arms journaled to the main shaft and to compressor rollers, a tension shaft in front of the upstanding arms carried on bearings from the main shaft, means connecting each arm to the tension shaft acting to turn this shaft as the beam grows, and means supported from the main shaft to restrain the turning of the tension shaft so as to maintain uniform pressure on the warp by the compressor rollers. C.

**Circular Independent Needle Knitting Machine Loop Forming Mechanism.** Hemphill Co. U.S.P. 2,337,153. The sinkers have two surfaces at different levels over which loops may be measured and drawn by the needles, and selecting mechanism is used to control the jacks so that they take either one or other of two pathways as they actuate the sinkers and cause short or long loops to be drawn. C.

**Circular Independent Needle Knitting Machine Yarn Feeding Mechanism.** Hemphill Co. U.S.P. 2,337,187. The claim is for a trimmer and binder, supported very close to and outside the circle of needles, but within the carrier ring, that is pivotally mounted so as to swing tangentially to and from a feeding position close to the needles and also to move upwards on being retracted from the needles and downwards on swinging in to feed. C.

**Raised Pattern Knitted Fabric.** Hemphill Co. U.S.P. 2,337,189. A plain fabric has portions standing out from the face wherein two yarns are knitted in consecutive courses, one in all wales and the other in spaced wales only, whilst in the remaining lower levels of the fabric both yarns are knitted in all wales, at least some of both areas occurring in the same courses. C.

**Plain Knit Elastic Fabric.** Hemphill Co. U.S.P. 2,337,211. The claim is for a fabric composed of alternate courses of (*a*) inelastic and (*b*) elastic yarns, (*a*) being knitted in every wale and (*b*) being knitted in alternate wales and tucked with loops of (*a*) in the other wales. C.

**Running Filament Liquid Treatment Device.** Grove Silk Co. U.S.P. 2,337,357. A strip of metal is bent medially and upon itself to form a kind of clip, and also bent into loops at the ends by which it can be supported in a pool of liquid. Capillary action causes the liquid to rise in the space between the two prongs and the yarn is carried through this portion of the liquid. C.

**Loom Beat-up Mechanism.** Crompton & Knowles Loom Works. U.S.P. 2,337,431. Means are provided to raise the reed with respect to the warp shed, first toward and then from the fell of the cloth, in timed relation with the picking motion. C.

**Bobbin Tube.** American Paper Tube Co. U.S.P. 2,337,438. The bobbin has a tubular barrel with outwardly flaring conical flange (*a*), an annular head (*b*) with conical counter-bore engaging (*a*), and an annular ferrule to hold (*a*) and (*b*) tightly together. C.

**Moulded Bobbin.** Kilgore Manufacturing Co. U.S.P. 2,337,770. A moulded, hollow bobbin is formed in two parts telescoped together and united to present a smooth, hard, resilient and substantially jointless surface for the yarn. At least one end is furnished along its inner edge with ratchet means. C.

**Loom Box Motion Lever.** Crompton & Knowles Loom Works. U.S.P. 2,337,896. The claim is for wedge means between the lever arm and a finger mounted on the arm, whereby a gudgeon on the other end of the finger is moved towards or away from the lever axis. C.

**Braiding Machine.** B. F. Goodrich Co. U.S.P. 2,337,977. The machine comprises a bobbin carrier, a single eye tensioning and guiding means for regulating the tension in the group of yarns as a whole, means for simultaneously applying tension to all the bobbins, and means controlled by the tension of a bight of a yarn for automatically relieving excessive tension on at least one of the yarns. C.

**Packing Braid.** E. I. Du Pont de Nemours & Co. U.S.P.2,337,986. The packing material comprises a number of ropes of continuous-filament regenerated cellulose rayon having an inherent and permanent crimp, the crimps in the several filaments being out of phase with each other. C.

#### 4—CHEMICAL AND FINISHING PROCESSES

##### (A)—PREPARATORY PROCESSES

**Soap: Application in Textile Processing.** Georgia Leffingwell and M. A. Lesser. *Rayon Textile Monthly*, 1944, 25, 188-189. Typical recipes are given in which soap is an ingredient of sizing, bleaching, dyeing, finishing and proofing agents. Relevant literature is briefly reviewed. C.

**Surface-active Agents: Application in Paper Making.** J. J. Miskel. *Paper Trade J.*, 1944, 118, TAPPI, 233-238. A useful review of the chemistry of surface-active agents of (1) the anionic (soaps, sulphated oils and esters, aliphatic alcohol sulphates and sulphonates, ester sulphates and sulphonates and alkyl-aryl sulphonates), (2) cationic (quaternary ammonium salts, etc.) and (3) non-ionic types (polyhydroxy alcohol esters and polyethylene oxide products), with special reference to applications in the paper industry. C.

**Textile Assistants: Application.** J. Hetzer. *Leipzig. Monats. Textil-Ind.*, 1941, 56, 132-134, 150-152, 174-175, 202-203 (through *Chem. Zentr.*, 1941, ii, 3014 and *Chem. Abstr.*, 1944, 38, 2503<sup>5</sup>). Methods are described for the softening of water, the prevention of the formation of calcium soap, the solution of calcium soap, the making of paste and solution of dyes, the preparation of emulsions, the washing of wool, carbonisation and fulling, the chlorination of wool, the protection of wool against moths and chemicals, the reserving of wool, the degumming of crude silk and its reserving. C.

##### (B)—BOILING, SCOURING, DEGUMMING, AND WASHING

**Silk: Degumming.** K. M. Markuze and V. I. Maleev. *Tekstil-Prom.*, 1941, No. 3, 36-39 (through *Chem. Zentr.*, 1942, ii, 1867 and *Chem. Abstr.*, 1944, 38, 2213<sup>6</sup>). The best degumming agent appears to be olive-oil soap, which forms stable emulsions, and can be readily removed by washing. The degumming properties appear to be due to the alkalinity of the medium rather than to detergent power.<sup>1</sup> In order to hasten the boiling-off process, the hydrogen-ion concentration should remain as nearly constant as possible during the operation. A buffer mixture of sodium carbonate and sodium bisulphite is recommended for this purpose. Three tables give details of the use of chemicals, results of the various tests, and the strength of the warp and weft of various fabrics. The advantages of the process depend on the rapidity of the operation at low temperatures and with low concentrations of soap solutions. C.

**Quaternary Compound Textile Assistants: Application.** G. Gaudry. *Ind. textile*, 1941, 58, 337, 380-381 (through *Chem. Zentr.*, 1941, ii, 3123 and *Chem. Abstr.*, 1944, 38, 2503<sup>7</sup>). Fixanol and Sapamin KW are suitable for the fixation of rubber on wool and for the improvement of the washing-fastness of direct dyeings on cotton. Lisolamine helps in the stripping of dyeings and Leukotrop OW, a dimethylbenzyl-ammonium chloride is used for coloured discharging on an indigo base; similar products with substituted benzyl groups are suitable for white discharging. Quaternary compounds can be used to cause cotton to absorb acid dyes. New quaternary compounds containing a fatty alcohol radical in the molecule serve as dispersing agents in vat dyeing. A compound for use as a retarding agent in vat dyeing comprises a benzoic acid derivative in which an aliphatic radical is joined to the main molecule by means of an ester group. Stable dull finishes on rayon can be obtained by means of surface-active compounds and zinc sulphate, barium sulphate or titanium dioxide. Wool can be impregnated with latex with the aid of quaternary compounds. C.

**Silk Waste: Degumming.** P. P. Viktorov and I. I. Kuhn. *Shelk*, 1940, 10, No. 11, 10-13 (through *Chem. Zentr.*, 1941, i, 3606 and *Chem. Abstr.*, 1944, 38, 2499<sup>8</sup>). Silk waste (50 g.) was placed in an autoclave at 50°, and boiled at 120° for 30 min. or at 130° for 60 min. The whole process including the heating of the water to 50°, boiling, cooling and washing of the sample took 2-2.5 hours. Boilings with neutral soap, with soap-soda mixture, with caustic soda, and with a mixture of caustic soda and commercial sodium bisulphite (38° Bé) were

studied. The boiled samples were cleaned and tested for strength, elongation and contents of sericin, fats, soap and ash. Comprehensive tables of experimental results are given in the original Russian paper. C.

**Synthetic Detergents.** F. D. Snell. *Soap*, 1943, 19, No. 10, 27-30, No. 11, 31-33, 74. The composition, characteristics (especially wetting and emulsifying power), and textile and other applications are described of the more common non-soap detergents (esters, ethers, amides, alkyl aryl sulphonates and cation-active agents). W.

**Scouring and Heavy Milling: Precautions against Stains.** *Dyer*, 1944, 92, 53-55. The scouring and milling is described of a special war-time cloth required to be finished in a natural wool shade to stipulated strength, pH value and thickness. A rubber roller scouring machine with a roller gap of about  $\frac{1}{8}$  in. was used to save the strength of the weft; details of processing treatment are given. To avoid stains in milling, all metal parts of the machine should be thoroughly cleaned, painted with a good quality aluminium paint and tightly wrapped with a clean material. Stains traced to the centres of the rollers can be avoided by dismantling the rollers, cleaning them and leading or galvanizing the iron parts; other methods consist of fitting thin brass or stainless steel plates over the centre, or of completely making up the centre opening by inserting wood pieces cut to shape. Stiff cloths may be stained by being forced against the back of the machine before falling into the bottom, and the back of the machine should therefore be well cleaned. Pieces may be forced out of the machine if the back door is not properly fastened, causing staining and possible damage to fabric if the rollers continue to revolve when the drafts have drawn tight. High temperatures may cause distortion of the wood parts of the machine, particularly the trough and its lid. W.

#### (C)—BLEACHING

**Hydrogen Peroxide Bleaching Bath Stabilizers.** P. Colomb. *Teintex*, 1941, 6, 222-226 (through *Chem. Zentr.*, 1941, ii, 3140 and *Chem. Abstr.*, 1944, 38, 2215<sup>2</sup>). A discussion of the patent and trade literature dealing with stabilizers such as  $\text{Na}_2\text{H}$  and  $\text{NaH}_2$  phosphates, boric acid, borates, aromatic amines, barium and magnesium salts, higher aliphatic alcohols, tin salts, starch, benzene and xylene. Practical examples for hydrogen peroxide bleaches with the addition of sodium pyrophosphate or phosphate are described. C.

**Sodium Bicarbonate: Application in "Souring."** A. L. Dubeau and H. R. Dinges. *Amer. Dyes. Rept.*, 1944, 33, 219-220. Advantages claimed for the replacement of sulphuric acid by 3 per cent. bicarbonate solution at 140-160° F. in (a) the open-width rinsing of heavy fabrics after scouring or mercerizing, (b) warp mercerizing, (c) removing caustic soda after kiering, and (d) removing caustic soda after steaming and before bleaching, in a new continuous bleaching process are (1) the possibility of hot washes, (2) relaxation of chemical control and (3) reduction of the number of steps, in some cases. C.

**Cellulose Fibre: Bleaching.** P. P. Viktorov. *Tekstil. Prom.*, 1941, No. 1, 46-48 (through *Chem. Zentr.*, 1942, ii, 2100 and *Chem. Abstr.*, 1944, 38, 2483<sup>4</sup>). The author starts from the idea that the alteration of physical properties of the cellulose fibre by chemical attack constitutes a deciding factor in its purification by bleaching. During the process of removing pectin from the cotton fibre, its physical condition is changed. Assuming a chemical bond between the cellulose and pectin, the author concludes that the rupture of this bond is accomplished with greater ease, yielding a better product, by treatment with oxidising agents and mineral acids rather than by boiling with caustic soda. The first method serves to spare the natural fats and waxes, leaving the elastic properties of the fibres intact. By subsequent treatment at higher temperature with a sodium hypochlorite solution, stabilised with water glass, a product completely free from lignin can be obtained. C.

**Percarbonates: Use in the Textile Industry.** J. Salquain. *Teintex*, 1942, 7, 164-166 (through *Chem. Zentr.*, 1942, ii, 1865 and *Chem. Abstr.*, 1944, 38, 2503<sup>3</sup>). Permonocarbonates are produced by the action of carbon dioxide on sodium or barium peroxide. Barium percarbonate, a pale-yellow, water-insoluble powder is decomposed by water into barium carbonate and hydrogen peroxide. Perdicarbonates are produced in 80 per cent. yield during the anodic oxidation of a saturated carbonate solution. Potassium perdicarbonate, blue

and hygroscopic, decomposes with the evolution of oxygen on heating; the addition of water at 50° produces hydrogen peroxide. The commercial product is a sodium perdicarbonate-hydrogen peroxide compound,  $\text{Na}_2\text{C}_2\text{O}_6 \cdot n\text{H}_2\text{O}_2$ . Per-carbonates in alkaline solutions are suitable for bleaching vegetable fibres, and in acid solutions for bleaching wool. They are suitable also as antichlor, for oxidising agents for vat leuco dyes, washing and boiling-out agents. C.

**Permanganate: Use in Bleaching.** G. Frische. *Deut. Färber-Ztg.*, 1941, 77, 273 (through *Chem. Zentr.*, 1941, ii, 2635 and *Chem. Abstr.*, 1944, 38, 2503<sup>41</sup>). The use of K permanganate in the bleaching and the spotting of fabrics, the treatment of cotton and rayon, the reduction by sulphur dioxide of the manganese dioxide formed, and the addition of magnesium sulphate during the bleaching of wool in order to bind the caustic alkali formed are discussed. For spotting, the sulphur dioxide is replaced by hydrogen peroxide, since the bleaching effect is increased by the double oxidation. C.

#### (I)—DYEING

**Aminoguanidine Azo Dyes: Production.** R. N. Shreve, R. P. Carter and J. M. Willis. *Ind. Eng. Chem.*, 1944, 36, 423-430. Aminoguanidine is obtained by electrolytic reduction of nitroguanidine. This is prepared by the dehydration with sulphuric acid of guanidinium nitrate which, in turn, is obtained from dicyandiamide. Aminoguanidine has been diazotised and hot-coupled with various intermediates, including  $\alpha$ - and  $\beta$ -naphthol and naphthylamine, Tobias acid, and *o*- and *p*-nitroaniline. Azo dyes having good dyeing properties on animal fibres, such as silk and wool, particularly in conjunction with a mordant, were obtained. When applied with a tannin mordant, the dyes gave chiefly brown and orange shades on wool. Tests indicated good fastness to light, rubbing, boiling acids, and dilute bleaching powder solution. C.

**Portable Dyehouse Equipment: Advantages.** Althouse Chemical Co. *Amer. Dyes. Rept.*, 1944, 33, 193-195 (from *Chem. & Met. Eng.*, 1944, January). An illustrated account of the advantages of "equipment on wheels" in the dyehouse, showing (1) a chlorine supply, (2) a filter press, (3) a pyrex heat exchanger, (4) a pump, and (5) a weighing machine. C.

**Cotton Yarn Packages: Vat Dyeing.** O. W. Clark. *Textile World*, 1944, 94, No. 4, 107-109. The factors that make for level package dyeing are analysed with the help of longitudinal sections of dyed yarn packages. These show (1) the influence of tightness of winding, (2) the advantage of increasing the rate of circulation from 2 to 4 and 8 gallons of dye liquor per package per minute, (3) the influence of the weight of the package (12, 20 and 32 oz.) and the advantage of increasing the rate of circulation, (4) the advantage, in some cases, of increasing the temperature of the bath (120 to 180° F.), (5) the advantage of slowly raising the temperature, from 70 to 120° F., with a dye that exhausts very rapidly at the higher temperature, and (6) the advantage of an appropriate dye-bath assistant. Suitable procedures are summarised for dyeing (1) slate blue on 500 lb. of 50s/4 cotton yarn, 24-oz. packages, without levelling agents, (2) baby blue on 100 lb. of 60s/3 mercerized Sakel yarn, 24-oz. packages, with the help of a levelling agent and a high rate of flow, and (3) green on 100 lb. of 40s/2, 24 oz. packages, without reversal of flow. C.

**Wollstra Yarns: Dyeing.** R. Hünlich. *Leipzig. Monatschr. Textil-Ind.*, 1941, No. 2, 34-35 (through *Chem. Zentr.*, 1941, ii, 2496-2497 and *Chem. Abstr.*, 1944, 38, 2211<sup>7</sup>). When washing of Wollstra yarns before dyeing is necessary, Igepon, Gardinol, Lamepon or a similar preparation may be used. If the wool is soiled with free fatty acids 0.25-0.75 g. of sodium carbonate per l. is added to the wash liquid. Preliminary bleaching is necessary only for white or light colours; this is done by treating the yarn first with potassium permanganate and magnesium sulphate, then with sodium bisulphite and formaldehyde. If the wool is to be dyed and the Vistra (rayon) to remain white, levelling and acid dyes are used; very fast colours are obtained with chrome dyes. If mixtures are to be dyed in which the wool and Vistra dye differently, either a 1- or a 2-bath method may be used. The wool is dyed with dyes which act predominantly on animal fibres when used in neutral sodium sulphate baths, whilst the Vistra is dyed with a suitable substantive dye by the addition of Katanol WL. When the two-bath method is used, the material is first dyed with the levelling or weakly acid dye and then dyed with the substantive dye in a fresh bath. Fast

colours are obtained by dyeing the Vistra with diazo dyes, diazotising and developing, then dyeing the wool with acid dyes in a boiling acid bath. C.

**Dyehouse Colour Matching Problems.** (1) F. T. Simon and E. I. Stearns. (2) Dorothy Nickerson. *Amer. Dyes. Rept.*, 1944, 33, 232-235, 251; 252-256. (1) The authors provide a series of answers to the general question "Why small colour differences are important in textiles," and point out the need for improvement in the "tolerance limits" to colour differences. (2) A summary is given of available information on the following formulæ for expressing small colour differences: (a) Nickerson's "Index of fading" (1936), (b) the same modified according to Balinkin (1941) to agree with Euclidean space, (c) the Judd index (1939), (d) the Hunter-Scofield modification of the Judd index (1942 and 1943), (e) based on Adams's "chromatic value" (1942), and (f) based on Adams's "chromatic valence" (1943). C.

**Bronze-like Indigo Dyeings: Production.** A. Simonet. *Teintex*, 1942, 7, 173-174 (through *Chem. Zentr.*, 1942, ii, 2088 and *Chem. Abstr.*, 1944, 38, 2493<sup>9</sup>). Bronze-like dyeings on cotton are produced by a ferrous sulphate-calcium oxide vat treatment. In order to use the more convenient hydro-sulphite vat the fabric is dyed first with a sulphur black, e.g. Noir Sulfanol extra conc. (Kuhlmann) or Aniline Black. Later it is dyed twice with Indigo NTS (Kuhlmann). C.

**Delustred Acetate Rayon: Improvement of Light-Fastness.** H. Lohmann and Paula Braun. *Zellwolle, Kunstseide, Seide*, 1941, 46, 90-92 (through *Chem. Zentr.*, 1941, i, 3586 and *Chem. Abstr.*, 1944, 38, 2496<sup>9</sup>). Rayons delustred with pigments are less resistant to light than are lustrous rayons, and many dyes are less fast to light on dull rayon. These differences in light fastness apply only to visible light; in mercury light the two fibres lose strength equally quickly. According to German and French patents of the Deutsch Acetat-Kunstseiden A.-G. "Rhodiaseta" the light fastness of rayons from cellulose or cellulose derivatives is improved by adding bivalent manganese salts to the spinning solution or by impregnating the fibre with the salts. C.

**Rayon Staple Fibre: Dyeing with Sulphur Dyes.** E. Köster. *Textilberichte*, 1943, 24, 265-266 (through *Chem. Abstr.*, 1944, 38, 2495<sup>9</sup>). Dyeings below 40° are not practical. Temperatures of 40-50° are recommended. Suitable Immediate dyes are listed and dyeing procedures are described. C.

**Spun Rayon Goods: Dyeing with Substantive Dyes.** H. Schumacher. *Textilberichte*, 1943, 24, 231-233, 268-271 (through *Chem. Abstr.*, 1944, 38, 2496<sup>9</sup>). Numerous dyes tested are tabulated and classified as cold-, intermediate- and hot-dyeing dyes. The dye-absorption velocity and the establishment of the state of saturation, large-scale test, the levelling of the dyeing, streakiness, localised inequalities, thorough dyeing of the fabric, fastness of the dyeing and saving in steam are discussed. The temperature of maximum dye absorption differs for the various dyes, and is not related to absorption velocity. The dye consumption does not increase, but may decrease in cold dyeing. The time needed for the establishment of the state of solution is approximately the same for cold and hot dyeing. Level dyeing and good penetration can be obtained less readily with cold-dyeing than with hot-dyeing dyes. The fastness of a cold dyeing, generally, is not inferior to that of a hot dyeing. C.

**Spun Rayon-Wool and -Cotton Mixtures: Dyeing.** W. Kegel. *Deut. Textil-wirt.*, 1941, 8, No. 14, 25-26 (through *Chem. Zentr.*, 1941, ii, 3123 and *Chem. Abstr.*, 1944, 38, 2495<sup>9</sup>). The pre-cleaning of spun rayon yarns with good wetting and washing agents and fat solvents, if necessary with the addition of some Oxycarnit L50 is discussed. Mixtures with wool can be dyed in a single bath with semi-wool dyes or in a double bath with diazo dyes and acid wool dyes. Mixtures with cotton are dyed with light-fast Sirius or Sirius Light dyes or washing-fast with diazotisation dyes. Fulling-fast dyeings are obtained with sulphur dyes; effects fast to light and washing are produced with indanthrene dyes. Spun acetate rayon is dyed with Celliton or Celliton Fast dyes; mixtures with wool are treated in single or double baths with the addition of acid dyes, and mixtures with cotton are dyed with cotton dyes "Type 8000." Acetate with semi-wool is dyed with the addition of Gardinol OTS or with Plurafil dyes with the aid of Igepon T. C.

**Superpolyamides: Action of Acids and Dye Acids.** E. Elöd and T. Schachowskoy. *Textilberichte*, 1942, 23, 437-440 (through *Chem. Zentr.*, 1942, ii, 2643 and *Chem. Abstr.*, 1944, 38, 2493<sup>5</sup>). Absorption of Crystal Ponceau 6R by superpolyamides increases strongly with increasing H-ion concentration; this increase, unlike that of the proteins, does not pass through a maximum. The swelling of the superpolyamides in water does not depend on the pH of the swelling medium; this also is different from the behaviour of proteins. Acid-binding property of superpolyamides increases up to a 2N hydrochloric acid solution without passing through a maximum. It is assumed that the NH<sub>2</sub> groups do not enter in these reactions, but that NH groups and adsorptive phenomena are responsible for these acid and dye acid reactions. C.

**Acid Colours: Tinctorial Aspects.** *Dyer*, 1944, 91, 429-431, 505-507, 515; 92, 24-27. The tinctorial function is discussed of the component acid colours in simple and compound shades of yellow, orange, pink, mauve and violet, blue, black, scarlet and green on animal fibres. Practical hints are given on choice of dyestuffs and methods of application, and corrective measures suggested for off-shade lots. W.

**Dyeing of Acid and Chrome Colours on Wool with Phosphoric Acid.** E. I. Noble. *Text. J. Australia*, 1944, 19, 71-77. A brief survey is given of the colloidal, semi-dispersed and dispersed dyes, and of the principles of their application. The behaviour of phosphoric acid in wool dyeing and the chemical theory of the process are discussed. Slubbing was dyed at 90° C. for 1½ hr. in a liquor to wool ratio of 30:1, to compare the dyeing properties of acetic, formic, sulphuric and phosphoric acids. The results showed that phosphoric (75 per cent. acid) may be used instead of formic and acetic acids with a large reduction in dyeing costs. It could replace sulphuric acid with better levelling and penetration and less damage to the wool and any cellulosic fibres present. Buffered with soda ash, it is suggested as a perfect substitute for acetic acid. It is a rustproofing agent, and when used with bichrome for dyeing chrome colours in dyeing machines containing iron, prevents rust and rust stains. The suggested volume requirements for sulphuric acid (96 per cent.), formic acid (90 per cent.) and acetic acid (60 per cent.) per 1 pint of phosphoric acid (75 per cent.) are sulphuric, 0.66, formic, 1, and acetic, 3. Calgon may be added to phosphoric acid dyebaths with advantage, particularly with chrome colours, thereby preventing possible dulling due to the traces of iron and some calcium sulphate which occur in the present war-time phosphoric acid made in Australia. W.

#### (J)—PRINTING

**Cotton and Rayon Piece Goods: Printing.** A. E. Hirst. *Cotton (U.S.)*, 1943, 107, No. 12, 79-82; 1944, 108, No. 1, 75-78; No. 2, 102-104; No. 3, 98-101, 114; No. 4, 109-112, 124; No. 5, 99-101; No. 6, 97-100. An illustrated review of modern practice under the headings (1) Preliminary processes (singeing, de-sizing, scouring, bleaching); (2) The white room (drying, dyeing, preparing colours); (3) Printing colours (dyes, thickeners, etc.); (4) Roller engraving; (5) The printing machine and its operation; (6) The ageing and soaping of piece-goods (with diagrams of the plant); (7) Finishing operations (stentering, calendering, Sanforizing, etc.). C.

**Formaldehyde-treated Spun Rayon: Printing.** M. Kerth. *Textilberichte*, 1943, 24, 233-234 (through *Chem. Abstr.*, 1944, 38, 2496<sup>8</sup>). Formaldehyde-treated spun rayon will give good results in alkali printing on a Naphthol AS base without any special pre-treatment, but such staple fibre is not suitable for printing with aniline black and diphenyl black. A pre-treatment of the goods with caustic soda improves its behaviour toward vat and Rapidogen dyes and also toward Anthrasol dyes according to the nitrite process. The use of caustic soda does not affect the swelling. C.

**Glucose: Application in Printing.** F. R. Naumov and T. E. Pisareva. *Khlopatobumazh. Prom.*, 1940, 10, No. 11-12, 41-43 (through *Chem. Zentr.*, 1941, ii, 2497 and *Chem. Abstr.*, 1944, 38, 2493<sup>7</sup>). Printing experiments were carried out with a glucose which contained 35-40 per cent. of reducing agents and therefore had about the same reducing power as hydrosulphite, although its manner of action was different. Hydrosulphite decomposes readily with the liberation of active hydrogen. Glucose, on the other hand, is itself reduced to alcohol by hydrogen. The aldehydic hydrogen of glucose readily combines with

oxygen, with conversion of the carbonyl group into an acid group. Printing experiments with vat dyes of Russian manufacture are described in detail. The results indicate that Bromo Indigo, Thio Indigo S, Thio Indigo Scarlet GG, Helindon Orange R, and Vat Red KH can be printed with glucose without essential change in shade. Indanthrene Yellow G, Indanthrene Golden Yellow GK, Indanthrene Brilliant Green B, Indanthrene Brilliant Violet RR, Indanthrene Dark Blue BO and Helindon Yellow all give satisfactory prints when the rongalite-glucose process is used. C.

#### (K)—FINISHING

**Rayon: Delustring.** J. Besançon. *Teintex*, 1940, 5, 299-300 (through *Chem. Zentr.*, 1941, i, 3462-3463 and *Chem. Abstr.*, 1944, 38, 2215<sup>1</sup>). Impregnating the fibres with barium hydroxide, washing and then treating with sodium stannate produces a dull finish fast to washing. Sodium stannate treatment can also be used with calcium salts. C.

**Chitosan: Preparation and Use as Fabric Dressing.** F. I. Sadov. *Tekstil. Prom.*, 1941, No. 2, 52-54 (through *Chem. Zentr.*, 1942, ii, 2101 and *Chem. Abstr.*, 1944, 38, 2215<sup>6</sup>). Chitosan, a yellow powder easily soluble in 1-2 per cent. acetic acid giving a highly viscous glass-clear mass, is obtained from chitin by treatment with caustic soda solution. Laboratory experiments indicate that chitosan can replace starch, yields a textile dressing that is relatively fast to washing, and gives a material with a good handle. The addition of copper sulphate to the dressing gives the finished fabric a greater strength when exposed to continuous effects of light. C.

**Finishing Mixtures: Composition.** G. R. Kaulen. *Tekstil. Prom.*, 1941, No. 4, 38-40 (through *Chem. Zentr.*, 1942, ii, 2101 and *Chem. Abstr.*, 1944, 38, 2215<sup>5</sup>). Finishing recipes used in Russian plants were considered to be irrational. The Central Scientific Textile Institute undertook to work out a uniform recipe which should be appropriate, inexpensive and effective. It consists of calcium chloride, vegetable oil, animal glue, Turkey red oil, stearin, glycerol, starch, fats and water. Details are given in three tables. C.

**Rayon Fabrics: Finishing; Softness Test.** Lucille Sklut and Barbara Hazard. *Rayon Textile Monthly*, 1944, 25, 181-182. Instruments for measuring properties related to the softness of fabrics are described and evidence is given of the value of the Planoflex and the Friction Meter (Dreby, 1942). This evidence is given in two tables that record tests (averages of 8) on the handle of a 146×80 4 and 1 rayon twill finished by soaking in 1, 0.5 and 0.25 per cent. solutions of Onyxsan (a cationic imidazoline derivative), D.L.-1 (a cationic quaternary ammonium compound), Mapromol (a blend of oleyl alcohol and sulphated oleyl alcohol) and Velvosheen (a sulphated oil). The cationic agents gave the greatest flexibility but fatty alcohols had not much more effect than plain water. The cationic agents also produced the greatest surface slipperiness and here the fatty alcohols almost equalled them. Many of the sulphated oils had little effect on slip. C.

**Acrylic Resins: Use as Finishing Agents.** H. Lachmann. *Kleppzig's Textil-Z.*, 1941, 44, 874-876 and *Textilber.*, 1943, 24, 362-364 (through *Chem. Zentr.*, 1941; ii, 2393-2394 and *Chem. Abstr.*, 1944, 38, 2501<sup>7</sup>). The finishing of vegetable fibres, finishing and finishing agents, the studies by Staudinger and Röhm on the polymerisation products of acrylic and methacrylic acids and the polymerisation of the monomeric esters of these acids are discussed. The hardness of the Plexigum acrylic resins increases from Plexigum D in the order B, A, P, N and M. These products can be used for finishing in solution or as aqueous dispersions. C.

**Cellulose Fabrics: Etherification Finishing Treatments.** L. Bonnet. *Ind. textile*, 1940, 57, 219-220, 254-256 (through *Chem. Zentr.*, 1941, ii, 1345 and *Chem. Abstr.*, 1944, 38, 2501<sup>3</sup>). Surface esterification is accomplished by treatment with fatty acid chlorides, e.g. with the chloride of stearic acid in the presence of pyridine. Alkyl ethers of cellulose are obtained by the action of solutions of the chloromethyl ethers of the higher alkyls in pyridine. When the chloromethyl ethers are allowed to react with pyridine, valuable water-resistant products of the type of Velan are obtained. Alkali-celluloses can be etherified with ethylene oxide. C.

**Finishing Agents: Application.** R. Sansone. *Deut. Textilwirt.*, 1941, 8, No. 14, 18-20 (through *Chem. Zentr.*, 1941, ii, 3141 and *Chem. Abstr.*, 1944, 38, 2501<sup>6</sup>). The Appretans give full, washing and rubbing-fast finishing effects. Appretan EMW is suitable for staple fibre, wool, cotton and mixed fabrics containing staple fibre. The finish becomes more pliable on addition of Appretan A, B or Z; also Soromin DF and DM are effective, especially the latter, which produces fullness without stiffness. Appretan EM takes the place of starch and dextrin and gives cotton fabrics a particularly strong feel. Fixappret B in conjunction with starch or glue improves the washing fastness. Appretan SF is not suitable for combination with starch and the like. Other softeners are Ramasit I and III. A suitable addition agent to starch is Tylose TWA 100, which makes it possible to employ large amounts of fillers. Good lustres during calendering are produced by the use of I.G. wax J.W.I. For soft finishing effects Soromin A, WF, N, AS, BS and S are used. C.

**Spun Rayon Fabrics: Effect of Steam and Pressure.** F. Günther. *Kunstseide u. Zellwolle*, 1941, 23, 184-185 (through *Chem. Zentr.*, 1941, ii, 973 and *Chem. Abstr.*, 1944, 38, 2500<sup>6</sup>). Staple fibre, unlike wool, does not expand again after being compressed. In washing operations the rollers must be light in weight and should not press the fabric very tightly. The fulling cylinders must be light. Excessive pressures and weights must be avoided in all finishing operations, pressing, etc. For the manufacture of high quality mixture yarns only curled staple fibre that produces bulky yarn of high heat-insulating properties should be used. C.

#### (L)—PROOFING

**Chlorinated Paraffin Fire-, Water- and Mildew-proofing Agents: Application.** A. E. Irvine. *Amer. Dyes. Rept.*, 1944, 33, 189-192. Chlorinated paraffins (e.g. "Halowax") with Cl content 42-45 per cent. are now widely used as fire-proofing agents. Other products contain 60-70 per cent. Cl. Their action is ascribed to their ready decomposition with evolution of hydrogen chloride. This is promoted by the presence of metallic oxides, especially those of Fe, Zn and Sb. When applied to fabrics, some means must be provided to protect the fibre from acid tendering; usually the addition of calcium carbonate is effective. The products afford some protection against mildew, but in proofing a more effective agent (e.g. Cu naphthenate) is usually added. Pigments and film-forming agents (for waterproofing) are made up with the other ingredients in a volatile solvent. The mixture is applied by means of squeeze rollers or doctor knives, set to secure a take-up of about 50 per cent., and the cloth is then dried in air ovens or over cans. A suitable formula is (A) the non-volatile vehicle: chlorinated paraffin 22-24 per cent., resin 7-8; (B) the pigment, catalyst, protective and mildew-proofing ingredients: colouring matter 4-4.5, antimony oxide 7-8, iron oxide 8-9, antiseptic 1; (C) the volatile vehicle: 43-37 per cent. of light mineral oil, Stoddard solvent, xylene or other solvent. C.

**Gutta Percha, Balata and Polyethylene: Applications.** J. N. Dean. *Textile Manufacturer*, 1944, 70, 314-316. A broad review is given of the sources, production and properties of gutta percha, balata and polyethylene, and possible textile applications. Physical data are tabulated. C.

**Neoprene and Other Synthetic Rubbers: Textile Applications.** E. H. Krisman. *Amer. Dyes. Rept.*, 1944, 33, 246-251. A broad review of the history of natural and synthetic rubbers, with special reference to the properties of Neoprene and its uses in belting, roller coverings, vibrationless mountings for machines, and other textile fields. C.

**Nylon Fabric: Coating.** *Textile World*, 1944, 94, No. 4, 112-113. Practical hints are given, helped by illustrations, on the spreading of nylon fabric with plastic coatings. The difficulties are due to (1) the recurrence of tight and slack places across the cloth, particularly manifested by slack centres and baggy selvages, (2) yarn slip, (3) tendency to curl in the drying oven, and (4) static electrification. A good practise is to fix a backing fabric (e.g. heavy duck) to the front tension bar at one side of the doctor knife, weighted with the back tension bar hanging in a fold on the other side of the blade. A light sizing coat may be applied to reduce yarn slip. Springy spreading wires slightly wider than the cloth may be pinned to the selvages by their pointed ends to prevent curling and wrinkling of the cloth during drying. Where the cloth passes over a roller, a fringe of thin chains may be dangled to dissipate static charges. C.

**Water-repellent Textile Materials: Behaviour of Water Drops.** A. Jaumann. *Kunstseide u. Zellwolle*, 1941, 23, 304-307 (through *Chem. Zentr.*, 1941, ii, 3141 and *Chem. Abstr.*, 1944, 38, 2215<sup>8</sup>). The behaviour of drops of water on different textiles, including some that were treated with water repellents, is shown by means of illustrations. Impregnations with Ramasit K conc. or with Persistol base + salt B did not allow the drops to penetrate even after prolonged standing. The double treatment of a velour chiffon of viscose rayon with the combination of Persistol and a Kaurit finish showed the fibres to have assumed the nap properties of silk. C.

**Spun Rayon Fabrics: Water-repellency and Swelling. Water-resistant Fabrics: Testing.** See Section 5C.

**Cotton Fabrics: Weather-proofing.** F. I. Sadov. *Legkaya Prom.*, 1940, 19, No. 11-12, 33-39 (through *Chem. Zentr.*, 1941, ii, 3014 and *Chem. Abstr.*, 1944, 38, 2500<sup>9</sup>). The extent of the loss of strength of cotton fabrics on exposure to the weather depends on the nature and the structure of the fabric, its chemical processing, the length of exposure, and the atmospheric conditions. The author recommends finishing treatments with (1) urea- or thiourea-formaldehyde resins, (2) copper sulphate hytosan finishing compound and (3) dicyanoformaldehyde resins. C.

**Rayon Fabrics: Rubberising.** — Kehren. *Textilberichte*, 1943, 24, 234-237, 274-277 (through *Chem. Abstr.*, 1944, 38, 2504<sup>5</sup>). The adhesion of the applied layer, the type of fibre from which the fabric was made, the nature of the rubberising, physical strength, and water extracts of rubberised goods are discussed. Simple curling-fast finishing and ordinary finishing for use in the tropics do not produce satisfactory results. Normal hydrophobing protects rayon only for a short time. A requisite for the service-ability of a rayon raincoat fabric is swelling-proof finishing, which must precede the water-repelling impregnation. The proper combination of suitable finishing and impregnation treatments can be determined only in large-scale tests. C.

**New Mothproofing Agents Containing Sulphonic Groups.** P. Langer. *Helv. Chim. Acta*, 1944, 27, 71-87 (through *J. Soc. Dyers & Col.*, 1944, 60, 190). The chemistry is discussed of mothproofing agents suitable for application by the methods used for dyes. These researches led to the discovery of Mitin FF (Geigy); the formula of which is:—

#### PATENTS

**Wool: Reducing Tendency to Felt and Shrink.** J. G. Mason, T. E. Thompson and Imperial Chemical Industries Ltd. B.P.561,475 of 22/5/1944. Wool and other animal fibres are treated, at any stage of manufacture or as garments, first in an aqueous solution of sodium chlorite and a wetting agent at <50° C., and then with hydrochloric acid at 90-95° C. To avoid discolouration, the mineral acid solution contains hydrogen peroxide, oxalic acid and/or tartaric acid. The material is finally bleached by immersion in an aqueous solution of sodium sulphite, sodium bisulphite, sodium hydrosulphite or sodium formaldehydesulphoxylate. Greatly reduced shrinkage properties are conferred, the tensile strength, elasticity and durability are not sensibly impaired, and the handle is only slightly inferior to that of untreated wool. W.

**Surgical Cotton Linting or Raising Machine.** C. Blair. B.P.562,287 of 22/1/1943:26/6/1944. A machine for linting or raising the pile on textile fabric, such as surgical lint or similar material, after the fabric has been bleached and made absorbent, consists essentially of a steel knife which is

moved to and fro over the flat surface of the fabric which passes from a roller over a tension bar and over a rubber pad beneath the knife-carrying bar, the fabric being drawn forward by a spiked roller. C.

**Water-sensitive Textile Materials: Production.** R. P. Roberts, E. B. Johnson and H. H. Taylor. B.P.562,386 of 27/11/1942:29/6/1944. A process for the manufacture of fabrics, yarns and other textile materials having a high degree of sensitivity towards water comprises treating a material having a basis of cellulose with an alkali and an etherifying agent so that the textile material retains its structure though the cellulose is converted into a cellulose ether which is capable of being swollen or dissolved by cold water. The treatment may also be applied to materials having a basis of a cellulose ester, especially cellulose acetate, the cellulose ester being both saponified and etherified in the course of the treatment. C.

**Photo-electric Cloth Length Measuring and Skew and Bow Correcting Apparatus.** British Thomson-Houston Co. Ltd. B.P.562,450 of 17/3/1943:3/7/1944 (Conv. 24/3/1942). Apparatus employed in the manufacture of material woven as a continuous strip comprising a series of similar sections separated by transverse portions having a light transmission characteristic which is materially different from that of those portions of the strip at opposite sides thereof, is provided with means for detecting variations in the length of the sections from a predetermined standard length comprising means for moving the strip longitudinally, means for causing a number of light beams to emanate from points of the strip spaced apart longitudinally thereof a distance equal to the standard length and means operative to give an indication in response to a time difference in the occurrence of corresponding variations in the light beams. Photo-electric devices may be arranged to receive the light beams and means responsive to a time difference in the output impulses of the photo-electric devices may be arranged to vary the relative speeds of strip moving means located at two longitudinally spaced points in order to adjust the lengths of successive strips. Means for correcting a departure from perpendicularity of the transverse portions or bands of the strip comprise further means engaging each side of the strip for moving it longitudinally, further means for producing light beams controlled by the passage of the transverse portions or bands of the strip and arranged on a line perpendicular to the strip and means responsive to a time difference in the occurrence of corresponding variations in the light beams for varying the relative speeds at which the two sides of the strip are moved. C.

**Nylon Crêpe Fabrics: Production.** British Nylon Spinners Ltd., G. Loasby and H. C. H. Talliss. B.P.562,555 of 7/12/1942:6/7/1944. Nylon fabrics showing crêpe and similar effects are produced by treating with a shrinking agent fabrics containing nylon threads that have previously been subjected to relatively mild treatment with formaldehyde, so that the various yarns in the fabrics will shrink by different amounts, the relatively mild treatment being such that the intrinsic viscosity of the treated threads can be restored to its original value by treatment with a dilute mineral or organic acid. Suitable shrinking agents include phenols, and formic, acetic, hydrochloric and sulphuric acids. After the treatment with a shrinking agent the fabrics may be treated with a dilute mineral or organic acid. The fabrics may contain in addition to formaldehyde-treated threads, untreated nylon threads and/or threads of other material, such as cellulose or silk. The shrinking treatment and/or the after-treatment with a dilute acid may be effected locally on the fabrics in order to produce novel pattern effects. Pleasing and novel pattern effects can also be obtained after dyeing the fabrics owing to differences in the dyeing affinities of the threads. C.

**Aqueous Synthetic Resin Dispersions: Preparation.** American Cyanamid Co. B.P.562,575 of 7/8/1941:7/7/1944 (Conv. 13/12/1940). A method of preparing stable aqueous dispersions of synthetic resins comprises preparing a liquid mixture of an alkyd resin having an acid number of 25 or more and an insoluble alkylated melamine-formaldehyde resin and adding to the mixture, with agitation, an aqueous solution of a proteinaceous emulsifying agent (e.g. ammonium caseinate) until an emulsion is produced. The proportion of alkyd resin may vary from 5 to 50 per cent. by weight. C.

**Alkali-soluble Carboxyethyl Cellulose Ether: Production.** Röhm & Haas Co. B.P.562,581 of 2/11/1942:7/7/1944 (Conv. 17/1/1942). A carboxyethyl cellulose ether that is insoluble in water but soluble in alkali is prepared by mixing within the temperature range 5° and 35° C., cellulose, a solution containing about 15 per cent. to about 40 per cent. of a strongly basic, insoluble hydroxide in an amount at least molecularly proportional to the glucose units of the cellulose, and about 0.2 to about 0.5 molecular proportions of acrylonitrile per glucose unit of the cellulose, until the reaction mixture is extensible with a 5 per cent. to 10 per cent. solution of a strong alkali hydroxide to form a substantially homogeneous solution or paste. C.

**Water-soluble Carboxyethyl Cellulose Ether: Production.** Röhm & Haas Co. B.P.562,584 of 5/11/1942:7/7/1944 (Conv. 17/1/1942). A water-soluble carboxyethyl cellulose ether is formed by reacting cellulose between 5° and 35° C. with an aqueous solution containing about 10-40 per cent. of a strongly basic soluble hydroxide and at least one molecular proportion of acrylonitrile per glucose unit of the cellulose, the amount of hydroxide being at least molecularly equivalent to the acrylonitrile reacting with the cellulose, until the reaction mixture is extensible with water to form a substantially homogeneous solution or paste even when acidified. C.

**Substantive Disazo Dyes: Production.** J. R. Geigy A.-G. (Basle, Switzerland). B.P.562,641 of 18/9/1942:11/7/1944 (Conv. 19/9/1941). Disazo dyes are obtained when 1 mol. each of a diazotised aminobenzene derivative with an *o*-positioned carboxyl group, but free from aroylamino groups, and of diazotised 6-chloro-2-amino-1-hydroxybenzene-4-sulphonic acid react in an alkaline solution with the condensation product from 2 mol. of 2-amino-5-hydroxynaphthalene-7-sulphonic acid with 1 mol. of phosgene or 1 mol. of cyanuric halide. In the latter case the third halogen atom, capable of reaction, may be replaced by an organic or inorganic residue, which latter does not take any active part in the dye formation, such for example as NH<sub>2</sub> or NHPh. The dyes can be coppered in the usual manner. As the diazotised amino benzene derivative, with *o*-positioned carboxyl group, but free from aroylamino groups, 2-aminobenzoic acid, or its substitution products such as 5-chloro-2-aminobenzoic acid or 5-nitro-2-aminobenzoic acid, may be used. Examples are given of the production of coppered dyes which give light-fast bluish red and Bordeaux shades on cellulose fibres. C.

**Diarylpyrrole Azo Dyes: Production.** M. Mendoza, M. A. T. Rogers and Imperial Chemical Industries Ltd. B.P.562,762 of 13/7/1942:14/7/1944. Azo dyes are made by coupling a diazotised arylamine with a 2,4-diarylpyrrole which may or may not be substituted in the 3-position. The dyes, especially those from arylamines containing in an ortho-position to the amino group a group which is reactive to metals, e.g. a carboxy or hydroxy group or a group convertible thereto, may be metallised. Acid wool dyes and direct cotton dyes of various shades, e.g. orange, brown, reddish brown and blue, can be obtained, which are of good fastness, particularly in the case of the metallised dyes. C.

**Crease-resisting Cellulose Textile Materials: Production.** Courtaulds Ltd. and J. Boulton. B.P.562,790 of 21/12/1942:17/7/1944. A process for the production of cellulosic textile materials having improved crease-resisting properties comprises impregnating the materials with a solution containing formaldehyde and urea or thiourea, either as such or in the form of their water-soluble intermediate product, together with an acid catalyst consisting of a mixture of boric acid and an aliphatic hydroxycarboxylic acid, such as tartaric or lactic acid, and thereafter subjecting the treated material to the action of heat to convert the formaldehyde and urea or thiourea or the water-soluble intermediate product into an insoluble condensation product. C.

**Fabric Embellishing, Conditioning and Processing Machine.** P. Shiel. B.P.562,937 of 2/3/1943:21/7/1944. A machine for embellishing, conditioning or processing fabrics comprises means for supporting the fabric between obstructions so that liquid, gaseous, or solid agents sprayed from nozzles past the obstructions or through apertures in the same produce some form of shape, edge, stencil, shadow, silhouette, spot, line or other aspect of the obstructions on both sides of the fabric. The effects obtained may be varied by varying the agents and the obstructions, and by altering the angle of diffusion, pressure and

position of the nozzles, maintaining the fabric at rest or imparting a continuous movement to it, and varying other conditions. C.

**Wool: Reducing Tendency to Felt and Shrink.** American Cyanamid Co. B.P. 562,977 of 25/7/1944. Wool or wool-containing fabrics are impregnated with a dispersion or solution of an alkylated methylol-melamine containing a catalyst. The material is then dried and cured at 200-300° F. Details are given of the shrink-resisting qualities imparted to a light-weight woollen flannel. Almost complete control of shrinkage may be had by using long curing periods and high temperatures. The shade of dyed wool and its fastness to light are unaffected, and the tensile strength of the wool is increased. W.

**Fabrics: Identification Marking.** National Marking Machine Co. Ltd. B.P. 563,098 of 16/4/1943:28/7/1944. (Conv. 11/5/1942). In a method of applying identification marks to fabrics, a thin sheet of rubber or like material capable of flowing under heat and pressure is interposed between the fabric and heated type which is pressed so that the material immediately adjacent the type face is separated from the sheet and forced into the fabric, the remainder of the sheet being finally removed. A sheet of tough flexible material, e.g. Cellophane, is preferably interposed between the heated type and the sheet of flowable material and secured to the latter. The rubber is coloured to contrast with the colour of the fabric. Identification marks applied in this way will withstand severe laundering, kier boiling, and other severe cleaning operations. C.

**Cellulose Derivative Fabrics: Anti-shrinkage Treatment.** C. Dreyfus. U.S.P. 2,337,652. Fabrics containing cellulose derivative yarns are scoured at 80° C. in an aqueous solution containing 60-90 gms. per l. of a neutral salt that inhibits swelling and a dispersing agent, and dyed in a bath containing a large amount of the same salt. The tendency of the fabric to shrink when wetted and dried is thereby minimized. C.

**Wool: Reducing Tendency to Felt and Shrink.** Prestige Ltd. Australian P. 117,933 of 17/12/1943. The desirable characteristics of wool are retained, and its felting properties largely eliminated, by acid halogenation under controlled conditions and in the presence of a substance, e.g. an aldehyde or soluble alcohol, which reduces the oxidation potential of the solution and lowers its pH value over the period of the reaction. The treatment plasticises the wool scales which are caused to adhere to the fibres. W.

**Wool: Reducing Tendency to Shrink and Felt.** Holeproof Ltd. Australian P. 118,223 of 2/3/1944. The wool is treated in a solution comprising an organic liquid (70-90 per cent. by weight of a monohydric aliphatic alcohol containing 2-5 carbon atoms), an inorganic or organic hydroxide dissolved in the liquid, and a polyhydric alcohol (glycerol or ethylene glycol) present in a concentration of not less than 5 per cent. by weight of the solution. The solution modifies the gelatinising effect of the alkaline substance, so that the original handle of the wool is substantially retained. W.

**Keratin-containing Materials; Protection from Pests.** W. Müller and W. Retter (to I.G. Farbenind. A.-G.). D.R.P. 716,599 of 24/12/1941 (through *Chem. Abs.*, 1944, 38, 2512). Dipyrzolonylphenylmethane compounds containing no amino, substituted amino or sulpho groups are used as the protecting substance. W.

**Mothproofing Fibres.** K. Brodersen and M. Quaedvlieg (to I.G. Farbenind. A.-G.). D.R.P. 735,092 of 1/4/1943 (through *Chem. Abs.*, 1944, 38, 1382). Heavy metal salts, preferably copper salts, of trithiocarbonic acid ( $\text{H}_2\text{CS}_3$ ) or its analogues with higher sulphur content are precipitated on the fibres. W.

## 5—ANALYSIS, TESTING, GRADING AND DEFECTS

### (A)—FIBRES

**Cellulose Hydrate Fibres: Structure.** H. Siebourg. *Zellwolle, Kunstseide, Seide*, 1941, 46, 215-223 (through *Chem. Zentr.*, 1941, ii, 1463 and *Chem. Abstr.*, 1944, 38, 2198<sup>3</sup>). The properties of artificial fibres are to be attributed not only to the degree of polymerization of the original cellulose and the X-ray orientation, but also to their internal structure. In order to gain some insight into the principles by which the various fibres are built up, studies were made of the rates of acetylation and solution of such fibres by treating them for about

10 min. with a 1:1 mixture of acetic acid and acetic anhydride after preliminary soaking. Examination of cross-sections of the fibres under the microscope revealed that, in most viscose rayons, the interior of the fibre was dissolved first, after which the surrounding external layers disintegrated. When an insufficient amount of the anhydride was used, only a very marked swelling was observed. Since it is impossible to reproduce the rate of solution of fibres to the second, it is recommended that a reference fibre previously dyed with Korinth RK or Brilliant Violet BBK be introduced with each test. Comparison of two fibres of the same origin showed that the fibre which was more resistant to wetting also withstood solution longer. With Schwarza and Lanusa fibres the solution process attacked all portions of the fibre cross-section simultaneously. Cuprama fibre behaved in a similar manner. Comparison of viscose fibres from 5, 7 and 10 per cent. solutions showed that fibres spun from the most dilute viscose dissolved first; fibres from the 7 and 10 per cent. solutions showed no difference in this respect. Of fibres stretched to various degrees, those which were stretched least dissolved first. C.

**Cotton-Viscose Rayon Mixtures: Quantitative Analysis.** F. P. Greenspan and S. M. Edelstein. *Amer. Dyes. Rept.*, 1943, 32, 73-76, 98. Work on a large number of viscose rayon samples from various sources showed that the ratio of the barium hydroxide adsorbed by viscose rayon to that adsorbed by a standard cotton yarn under identical conditions was fairly constant. This adsorption ratio when obtained under a particular standardised set of conditions and multiplied by 100 is known as the Barium Activity Number. Since the adsorption varies with the equilibrium concentration, the Barium Activity Numbers are corrected to the same final equilibrium concentration of barium hydroxide and then designated "Hydroxide Adsorption Numbers." All viscose rayons give the number 348 with a negligible error whereas unmercerised cottons give the number 100. For the analysis of mixtures, the Hydroxide Adsorption Number of the unknown sample is determined and the percentage of each fibre is calculated from this result and the numbers 100 and 348. Details of the experimental procedure and calculations are given. Analyses of various known mixtures by this method indicate good results, within the accuracy desired for mill and testing laboratory work. The greatest error is found with mixtures containing a large percentage of rayon. The procedure with the constants as given is applicable to mixtures containing unmercerised cotton, but not to mixtures containing mercerised cotton, which has a Hydroxide Adsorption Number of 100-165 according to the degree of mercerisation. It can, however, also be used for the analysis of linen-rayon mixtures since linen has a Hydroxide Adsorption Number of 100. In mixtures of rayon and cotton containing also wool, or silk, or both, the silk and wool may be removed by treatment with hot 5 per cent. caustic potash or soda, and the residue analysed as above, since the caustic treatment does not affect the Hydroxide Adsorption Numbers of rayon and cotton. C.

**Rayon: Alkali Solubility; Determination.** E. Kühnel. *Kunstseide u. Zellwolle*, 1941, 23, 235-242 (through *Chem. Zentr.*, 1941, ii, 2157 and *Chem. Abstr.*, 1944, 38, 2216<sup>4</sup>). A critical review of the usual methods of determining alkali solubility showed that they had no relation to the behaviour of the fibres in wash liquors and were, besides, exposed to numerous sources of error. A new method is to treat the fibres for 1 hour at 20° with a 10 per cent. solution of caustic soda, centrifuge, wash twice more with 10 per cent. caustic soda then with saturated sodium sulphate solution, make acid with acetic acid, wash with water, dry and weigh. But even the 10 per cent. concentration of caustic soda showed no relation to the solubility characteristics of different fibres. Further experiments showed the unsuitability of caustic soda solutions even at lower concentrations. Good results were obtained by boiling 1 hour under the reflux condenser with 0.2 per cent. sodium carbonate solution. The fibre residue was filtered and an aliquot portion titrated with 0.1N permanganate to a rose colour. The factor (obtained with glucose) is 2.27; c.c. 0.1N permanganate  $\times$  2.27 = per cent. soluble ingredients. Repeated boiling tests on the same sample showed that intermediate drying increased the solubility. Practical washing and wearing tests showed good agreement with the new method. C.

**Flax Cellulose: Fluidity Determinations.** W. A. S. White and T. N. Richardson. *J. Textile Inst.*, 1944, 35, T53-60. C.

**Fibres: Moisture Absorption.** W. Bobeth. *Kleppzig's Textil-Z.*, 1941, 44, 975-982 (through *Chem. Zentr.*, 1941, ii, 3144 and *Chem. Abstr.*, 1944, 38, 2212<sup>b</sup>). Experimental work is described and results are given for average moisture absorption at 65 per cent. R.H. for various fibres. These values are recommended to take the place of standard regains in calculations of quantitative chemical analyses of mixture fabrics. C.

**Fibres: Structure.** G. Vogt. *Kunstseide u. Zellwolle*, 1942, 24, 404-412 (through *Chem. Zentr.*, 1942, ii, 2865 and *Chem. Abstr.*, 1944, 38, 2211<sup>b</sup>). Layers, fibrillae, chain molecules, micelles and atoms in the construction of natural fibres are described. The influence of the layers of fibrillae on the technical properties of fibres are discussed. Artificial fibres do not need to be exactly the same as natural fibres in all details of structure, but it appears to be necessary to realise the fibrillar structure in some form. C.

**Cellulose: Chemical Constitution and Physical Properties.** G. Dierkes. *Kunstseide u. Zellwolle*, 1941, 23, 243-248; *Deut. Wollen-Gewerbe*, 1941, 73, 857-862 (through *Chem. Zentr.*, 1941, ii, 3015 and *Chem. Abstr.*, 1944, 38, 2483<sup>b</sup>). The author attempts to correlate the chemical constitution of cellulose with a series of physical properties of cotton, staple fibre and filament rayon, such as tearing strength, stretchability, swelling tendency, lustre and viscosity. C.

**Cotton Linters: Degradation; Determination.** R. Béha. *Ind. textile*, 1941, 58, 335-336 (through *Chem. Zentr.*, 1941, ii, 2275 and *Chem. Abstr.*, 1944, 38, 2486<sup>b</sup>). Methods are described for determining  $\alpha$ -cellulose, copper number, methylene blue absorption and alkali solubility. A high consumption of methylene blue occurs with a large content of lignified fibres; raw cotton has a high methylene blue number. Markedly degraded fibres show a high alkali solubility. There is a direct relationship between the copper number and the  $\alpha$ -cellulose content. C.

**Damp Stored Cotton: Deterioration.** C. Nanjundayya. *Indian Textile J.*, 1944, 54, 309-312. The author stored samples of Surat 1027 A.L.F. cotton, raw, hand picked, solvent-extracted (de-waxed) and scoured (de-pectinized), under sterile conditions over brine at  $33.5 \pm .5^\circ$  C. (=97 per cent. R.H.) for periods up to 4 months and measured their fibre-bundle strength, fluidity, copper number and moisture content. The results are tabulated and treated by the analysis of variance. The raw cotton suffered a considerable loss in strength and copper number, but little increase in fluidity. The de-waxed and de-pectinized samples suffered a fall in copper number, but the other characters were not much affected. The moisture content of the raw cotton progressively increased in storage. It appears that the non-cellulosic constituents undergo a change that affects the copper number and moisture content but not the fluidity. C.

**Fibre Identification Stains: Effect of Textile Finishes.** B. Norwick. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 274. Finishing treatments produce changes in the colours shown by rayon fibres on treatment with stains. When the nature of the fibre is known, anomalous dyeing may serve to determine the finish or the extent of processing. A table is given showing the colours given by acetate and viscose rayon materials with the Davis and Rynkiewicz stain after caustic treatments at different concentrations and temperatures. Tables are also given showing the possible significance of various colours produced with this stain and the colours given by various sizing materials. Cotton, dried with formaldehyde and a trace of acid, moistened with ammonia, and then heated either in an oven or in an organic liquid such as lauryl alcohol, quickly loses its ability to pick up blue from the stain and shows first reddish shades and then yellows. Drying cotton with glyoxal gives similar results. The presence of melamine on cotton causes the latter to pick up yellow. Drying viscose with glyoxal yields a yarn which dyes a pale yellow. The common creaseproof and shrink-resisting urea-formaldehyde finish gives yellow shades. Incomplete and uneven desizing can be rapidly detected on known fabrics of nylon, viscose and acetate rayon, since the common size materials stain a deep, contrasting blue. C.

**High-polymer Filaments: Structure.** F. H. Müller. *Forsch.-Ber. Zellwolle-u. Kunstseide-Rings G.m.b.H.*, 1942, No. 1, 65-69 (through *Chem. Zentr.*, 1942, ii, 2102-2103 and *Chem. Abstr.*, 1944, 38, 2498<sup>a</sup>). High-polymer products contain-

ing fibrous molecules are assumed to contain molecular nets and felt-like structures, but no micelles or crystallites. The arrangement of the netting-like structure is characterised by a function which indicates the distribution of the monomeric residues in their steric orientation. A state of orientation is considered to be a static equilibrium between orientating tendencies and temperature movement. The spinning process is discussed on the basis of these studies. C.

**Insulating Silk: Testing.** Y. N. van-Haut. *Shelk*, 1940, 10, No. 11, 21-23 (through *Chem. Zentr.*, 1941, i, 3606 and *Chem. Abstr.*, 1944, 38, 2499<sup>6</sup>). The conductivity and acidity of aqueous extracts of several grades of dyed silk, their hygroscopic properties, ash contents, and the insulating resistance of cables at 80 per cent. relative humidity were studied. Specific resistance of aqueous extracts at 20° should not be below 25,000 ohms/cm. (Extract 2 g. of silk at 96-97° for 2 hours using a reflux condenser, with 80 c.c. of water, and determine the conductivity with the Coulé or Kohlrausch bridge). The moisture content at 80 per cent. R.H. should not exceed 11.5 per cent. The time for the moistening of the sample according to a standard procedure should not be less than 4 days. No mineral acids should be present. The amount of organic acids calculated as acetic acid should not exceed 0.02 per cent. To determine these, extract with a reflux condenser at 100° for 2 hours or at 45° for 30 min. (provisional standard), and titrate potentiometrically. C.

**Silk: Effect of Electrolytes on Electrical Conductivity.** G. R. Vishnevetskii. *Legkaya Prom.*, 1940, 19, No. 11-12, 44-47 (through *Chem. Zentr.*, 1941, ii, 3014 and *Chem. Abstr.*, 1944, 38, 2498<sup>7</sup>). The introduction of electrolyte into silk fibre by treatment with N.-sodium sulphate solution has the same effect on the electrical conductivity of the fibre as does an increase of atmospheric humidity by 15 per cent. Sodium chloride has a still greater effect on the conductivity of silk. Silk treated with sodium chloride has the same conductivity at 40 per cent. R.H. as untreated silk at 70 per cent. R.H. C.

**Spruce Processionary Caterpillar Silk: Characteristics.** G. Gallese. *Textilia* (Milan), 1940, 16, 495-496 (through *Chem. Zentr.*, 1941, i, 3605-3606 and *Chem. Abstr.*, 1944, 38, 2499<sup>4</sup>). The fibre of the cocoon of *Thaumetopoea processionea* has a silk-like lustre, is gray to yellowish, and is microscopically similar to the bombyx fibre. Its average tensile strength is 1.95. It is soluble in water at 120° and water at 45° dissolves 11.25 per cent. after 12 hours; the solution is chestnut brown, is faintly acid, contains 10.05 per cent. of dry material (120°) and yields 1.75 per cent. ash. Boiling with water for 1 hour dissolves 22-34 per cent. of the fibre. The fibre is soluble in cold caustic soda, warm soda solution and soap solution. Zinc chloride first turns it brown and then dissolves it. The fibre cannot be used as a textile raw material but may possibly be employed as a substitute for kapok. C.

**Animal Fibres: Identification in Medico-legal Cases.** J. L. Stoves. *Medico-legal and Criminological Rev.*, 1943, 11, 185-191. Examples are given showing the importance of fibre histology in forensic science. Methods of identification are described for various non-human mammalian hairs, preliminary examination being microscopic and chemical, and histological examination involving the study of transverse and longitudinal sections and of superficial scale structure. Typical results are illustrated by photomicrographs. W.

**Australian Merino Wool: Crimp-fineness Relationship.** W. R. Lang. *Pastoral Rev.*, 1944, 54, 78-79. The Gordon Institute of Technology, Geelong, Vic., has surveyed 1,373 staples, representing a very fair cross-section of the Australian merino clip. Each sample was measured under the micro-projector at x/350, and the mean thickness calculated from 250 observations. The quality number was allotted from Duerden's quality number-thickness scale for S. African wools, and the number of crimps per in. compared with his crimp-quality scale (this *Journal*, 1929, 20, T93). The analysis of the results as compared with those of Bosman (this *J.*, 1937, 28, P270) showed that Australian merino wools had a closer crimp-fineness relationship (28 per cent. agreement) than S. African (16 per cent. agreement). W.

**Wool Yields from Four Breeds of Sheep.** E. M. Pohle and L. N. Hazel. *J. Animal Sci.*, 1944, 3, 159-165. Clean wool yields of whole fleeces and of small samples from 8 body regions were compared, the breeds used being the Rambouillet, Targhee, Corriedale and Columbia. The average yields were highest

from the shoulder, hip, thigh and belly for all 4 breeds, and lowest from the withers, back, rump and side for most of the 4 breeds. The average yield of the whole fleece for the 4 breeds was 38.6 per cent. There was a highly significant difference of 3.4 per cent. between the average small sample and whole fleece yield, breed differences and differences among sheep within the breed also being highly significant. The most accurate coefficients for predicting whole fleece yields appeared to be the *a* and *b* values for a particular region averaged for the 4 breeds. The withers, back and rump were the least desirable regions for taking small samples, the differences in accuracy among the other regions being so small that choice may be decided by ease of sampling. W.

**Shrinkage and Value by Grades for 1943 Range Wools.** E. M. Pohle and H. R. Keller. *Sheep & Goat Raiser*, 1944, 24, No. 8, 8-10. The 1943 wool clip of the U.S. Sheep Experiment Station and Western Sheep Breeding Laboratory, Dubois, Idaho, was graded at shearing and scoured in a commercial plant, and the wool was then appraised and sold on a scoured, sorted basis. Data are given on the shrinkage and appraisal values from 3,482 fleeces produced by the Rambouillet, Targhee, Corriedale and Columbia breeds. W.

**Wool: Determining Shrinkage.** J. V. Christensen and A. C. Esplin. *Farm and Home Sci.*, 1943, 5, No. 4, 5, 11 (through *Exper. Sta. Rec.*, 1944, 90, 716). Composite sampling for flocks of sheep and side sampling for individual, particularly purebred, sheep, with subsequent wool shrinkage studies, showed the need for sampling clips of each grower to determine a fair market price for wool, and also showed that breeding stock should be selected for length of staple as well as weight of fleece. Tables show (1) range in shrinkage of wool from samples from 25 flocks by grades; (2) variation in grease weight, scoured weight, staple length and shrinkage in 373 sheep from 4 pure-breed flocks of Rambouillets; (3) comparison in production based on staple length. W.

**Fleeces of Navajo Sheep: Preliminary Report on the Post-natal Development of Fibre Characteristics.** J. O. Grandstaff and C. T. Blunn. *J. Animal Sci.*, 1944, 3, 194-200. Samples from the side, thigh and back of 15 Navajo ewe lambs were measured, at intervals of 28 days to one year of age, for percentages of wool, hair and kemp, and the diameter distributions determined. At 28 days the samples averaged 60 per cent. wool, 24 per cent. hair and 15 per cent. kemp; during the next 56 days wool increased 21 per cent. and hair and kemp decreased 9.5 and 10.5 per cent. respectively; from 84 to 364 days the proportions of the 3 types remained relatively constant. The diameter distributions for wool and hair did not change significantly during the year, but kemp showed a significant change in distribution between the 28 and 56 day samples. W.

#### (B)—YARNS

**Silk Yarns and Fabrics: Analysis for Acids and Chlorides.** G. Baroni. *Seta*, 1941, 47, 127-129 (through *Chem. Zentr.*, 1941, ii, 2637 and *Chem. Abstr.*, 1944, 38, 2213<sup>8</sup>). The total acids were determined by titration of an aqueous extract of 10 g. of yarn or fabric with 0.1N. caustic soda using phenolphthalein as indicator. The results were expressed as sulphuric acid per 100 g. of dry material. To determine the free sulphuric acid separately a 50-g. sample was repeatedly extracted with lukewarm water and the combined extracts were evaporated to about 10 c.c. Two c.c. of this solution were placed on a 7-cm. filter paper, which was then dried at 100°. If the paper darkened or became brittle, the presence of free acids ( $\text{HCl} + \text{H}_2\text{SO}_4$ ) was indicated. The remainder of the concentrated solution was evaporated in a platinum dish and dried for 2 hours at 150°. The residue was sulphuric acid. In order to determine hydrochloric acid quantitatively the extract of a 50-g. sample of yarn or fabric was distilled with steam and the hydrochloric acid titrated in the distillate. In the absence of free sulphuric acid, chlorides could be determined directly with silver nitrate in the residue from the steam distillation. Otherwise, chlorides were determined as free hydrochloric acid after distillation with steam. C.

**Yarn Calculation Tables.** E. Whitworth. *Textile World*, 1944, 94, No. 4, 102-103. The following "ready reckoner" tables are provided: (1) Number of yards per lb. of worsted yarn ranging in counts from 1 to 99. (2) Ditto for cotton, counts 1-120. (3) Deniers equivalent to skein lengths of 100, 120, 200 and 300 yards and weights ranging from 1 to 9 grains. C.

## (C)—FABRICS

**Dial-reading Steelyard-type Strength Testing Machine.** S. Denison & Son Ltd. *Textile Manufacturer*, 1944, 70, 304-305. A detailed, illustrated description is given of a testing machine that can be fitted with jaws for cloth, webbing, tapes, cord, etc., and is constructed in the range of 600, 2,500, 5,000 and 8,000 lb. capacity. The top jaw is connected by knife-edge levers and links to a steelyard which is also linked to a dial pointer that indicates the load directly. Pull on the other jaw is effected through hydraulic gear which may be worked from the water main for the lightest models or through a motor-driven oil pump with constant or adjustable piston. Constant rate of load mechanism (B.P.560,832) comprises a trolley having rear wheels that run on fixed rails and a front wheel that rests on the steelyard. The trolley is motor driven so as to keep the steelyard floating. The knife edge of the steelyard can be adjusted so that the machine capacity can be made one-half, one-fifth or one-tenth the full capacity. The dial is divided into 600, 500 or 800 divisions. That for the 8,000-lb. machine has 800 divisions, so that each division means 10, 5, 2 or 1 lb., according to the knife-edge setting. The machine can also function as a constant rate of traverse type by adjusting the hydraulic pump gear. An autographic load/extension recorder with load ordinate vertical can also be fitted. C.

**Light-weight Fabrics Compression Meter.** E. C. Dreby. *Amer. Dyes. Rept.*, 1944, 33, 199-204. A description is given of an instrument for testing the compressibility of soft, light-weight fabrics under pressures between 0.05 and 0.50 lb. per sq. in. The main part is a metal cylinder with a conical cavity, the base of which is closed by a rubber membrane, 3 in. diameter and 0.004 in. thick. This part is hinged at one point and can be brought down on the fabric, which is clamped in a ring over a base plate. The cavity is filled with an 8 per cent. solution of potassium dichromate which rises at the apex of the cone into a graduated glass capillary tube (about 1 mm. bore). The top of this tube is fitted with a needle valve. The cavity is filled through a well to one side of the central tube. Opposite this opening is another well closed by a micrometer screw, the stem of which (0.25 in. diam.) acts as a piston to make a fine adjustment of the air pressure on the liquid and therefore of the height of the column in the capillary tube. This tube is graduated in units of 0.05 lb. per sq. inch by clamping a pan to the base of the instrument and connecting it through a side tube to a vertical glass tube in which known heads of water can be established. Tests on fabrics are made at a controlled temperature, since a fluctuation of 5° F. would introduce an error of 10 per cent. or more. To make a test, the needle valve is opened and the micrometer is turned until the level in the capillary is raised to the lowest graduation. Half a minute is allowed for the system to establish itself and the micrometer is then adjusted to get the liquid in the capillary on the mark. The micrometer setting is read and the liquid in the capillary is then brought to the other graduations in succession, up to the top and down again, and the corresponding micrometer settings are noted. The compressibility of the fabric is given by the equation

$$\text{compressibility} = \frac{a(R_1 - R_2) - V}{A.T.M. (P_2 - P_1)}$$

where  $R_1$  and  $R_2$  are the micrometer readings at pressures  $P_1$  and  $P_2$ ,  $V$  is the volume of liquid in the capillary equivalent to  $(P_2 - P_1)$ ,  $a$  is the area of cross-section of the micrometer stem,  $A$  the area of fabric covered by the rubber membrane,  $T$  the thickness of the fabric measured by an ordinary dial gauge instrument under a pressure of 1 lb. per sq. in., and  $M$  is a constant (the units are inches, sq. in., cub. in., and lb., according to the context). For comparisons, however, as in the ranking of a series of fabrics according to "handle," the simple difference in micrometer readings between the values for 0.05 and 0.45 lb. per sq. in. may be used; this is called the "compression meter value." Results are recorded for a series of 80 × 80 cotton percales, arranged in order of "fullness" as judged by trained men, and for a set of four cotton fabrics, 100 × 56, and two spun rayon fabrics. The relationship of the compression measurements to flexibility tests by the "Planoflex" is indicated in the tables. C.

**Cellulose Materials: Determination of Degree of Damage.** (1) O. Eisenhut. (2) H. Vetter. *Textilberichte*, 1941, 22, 424-426; 426-428 (through *Chem. Zentr.*, 1941, ii, 2274 and *Chem. Abstr.*, 1944, 38, 2212<sup>7</sup>). (1) The most accurate method for determining the damage to fibres by chemical agents is the observation of the change in the average degree of polymerization. A formula for determining the damage factor is developed and a table shows the damage to cotton produced by different treatments, such as bleaching, hydrolysis and washing. By this method it is possible to express numerically any kind of chemical damage to cellulose and thus to compare the method of action of such processes. (2) Nomograms are given for quickly and accurately determining the degree of damage of fibrous materials. C.

**Moist Knitted Underwear Fabrics: Thermal Properties.** C. W. Hock, A. M. Sookne and M. Harris. *Amer. Dyes. Rept.*, 1944, 33, 206-219. It is generally recognized that fabrics of comparable thicknesses and densities do not vary much in thermal resistance, but that moist fabrics vary considerably in the extent to which they create a "clammy feel" in contact with the skin. This property has now been investigated on a series of knitted underwear fabrics, particulars of which are tabulated. They include cotton, wool, cotton/wool mixtures, and pure viscose, acetate and nylon rayon fabrics. The particulars include measurements on twice-laundered materials, of weight, thickness under 0.1 lb. per sq. in. pressure, air permeability (Schiefer and Boyland instrument) and thermal transmission (Cleveland instrument). Three types of test are reported. (1) *Subjective tests*. Fabrics containing 100, 150 and 200 per cent. of moisture (based on the conditioned weights) were compared in pairs, one on each forearm, by five men, in a room at 21.1°C. and 65 per cent. R.H. The initial impression of chill and of a difference between the two arms was recorded. (2) *Physical tests*. An apparatus is described in which the upper half of an oil bath, maintained at  $50 \pm 0.05^\circ\text{C}$ . was covered by asbestos sheeting and a layer of rubberized cloth on which were laid four copper-constantan thermal couples, the whole forming a "skin"  $\frac{3}{8}$ -in. thick, the surface temperature of which (mean of the four thermo-couples) remained at  $37.5^\circ\text{C}$ . when exposed to the draught created by a fan blowing air over a water-cooled radiator. Specimens of the cloths,  $3\frac{1}{2} \times 6$  ins., were wetted and squeezed out until they contained 150 per cent. of moisture, and then laid over the "skin" and held in position under strips of cheesecloth having weights of 0.3 lb. hanging from each end. The changes in "skin" temperature were observed at intervals from 30 seconds to 10 minutes. Results are given in a series of eight graphs. (3) *Contact tests*. To assess the closeness of contact between the fabric and the "skin," a soft paper (particulars given) was prepared by steeping in the colourless suspension obtained by grinding basic fuchsin and rubber in Stoddard solvent. The dry paper ( $3\frac{1}{2}$  ins. square) was laid on a glass plate, covered with the moist fabric and another glass plate, and weighted to make the pressure of contact equivalent to 0.5 lb. per sq. in. After 10 minutes the paper was inspected and measured photometrically to give a figure for the colour developed by contact with the moist fabric. Photographs of the papers are reproduced for all the cloths, containing 200 per cent. of moisture, and a series of eight graphs show per cent. reflectances plotted against per cent. moisture (up to 400 per cent.). The main conclusion drawn from the investigation is that the "chilling effect" is directly connected with the closeness of contact. The advantage of wool lies in its natural ability to minimise this and the chilling effect of wet cotton fabrics can be lessened appreciably by giving them a napped or fuzzy surface. C.

**Spun Rayon Fabrics: Water Repellency and Swelling.** A. Zart. *Zellwolle, Kunstseide, Seide*, 1941, 46, 180-182 (through *Chem. Zentr.*, 1941, ii, 1463-1464 and *Chem. Abstr.*, 1944, 38, 2215<sup>9</sup>). In order to measure the water repellency of chemically treated spun rayon fabrics the pressure necessary to force water through a definite thickness of the material was determined. Disks of the material were securely fastened between nickel screens, and water pressure on the under surface was slowly and uniformly increased by raising a levelling bulb until water just appeared on the upper surface. This point was taken as the reading. The pressure required at first increased with increasing weight of the material and then remained constant beyond a definite weight. It was necessary to avoid reverse changes in pressure. The recorded pressure was independent

of the time during which it was applied. It was necessary to keep the effective surface of the disk, the weight of the material and the rate of uniform increase in pressure as constant as possible. With increasing titer the water repellency and the effective surface, calculated on the same weight of material, decreased. Treatment with boiling soap-soda washing solutions only slightly decreased the water repellency. Treatment with formaldehyde produced a very sharp reduction in swelling, but only very slight ability to repel water. Swelling values and water repellency are reported in tables. It is advisable to discontinue use of the term "hydrophobic" in this connection. C.

**Water-resistant Fabrics: Testing.** G. A. Slowinske. *Amer. Dyes. Rep.*, 1943, 32, 85-91. Measurements were made with a hydrostatic pressure tester, an air permeability tester (a commercial Densometer), and a new impact penetration tester in which the fabric is placed over an absorbent blotter and subjected to a spray of water, the amount of water passing through being determined by weighing the blotter. Photographs of the three instruments and diagrams showing details of the impact penetration tester are given. Measurements are recorded on 50 cotton fabrics which had been processed under the same conditions with the same concentration of a commercial water repellent and were rated "100" in the spray test of the American Association of Textile Chemists and Colorists. It is assumed that the results obtained in the impact penetration and hydrostatic pressure tests on these fabrics are related to the effects of fabric construction. No real relationship appears to exist between the results obtained with the three instruments. Results obtained for series of poplins and twills, suggest that the data in the three tests are inter-related for a single weave of fabric, and that when one weave is considered it is possible to predict the relative performance of a water-resistant fabric, even before it is treated, from the air permeability of the untreated fabric, since water-repellents do not change the air permeability to any appreciable degree. Hydrostatic pressure data for a number of twills treated with two different water repellents show that the order of performance is the same with the two products. Other work has shown that the same relationship holds for fabrics of different weaves treated with different water repellents. This makes it possible to choose a fabric for use in, e.g. a raincoat, without first deciding what water repellent will be specified. For evaluating or predicting the performance of a water-resistant fabric intended for use in garments subjected to outdoor wear it is necessary to consider (1) resistance to wetting of the fibres and yarns, (2) resistance to the passage of water under static pressure, and (3) resistance to the passage of water under impact or dynamic pressure. Resistance to the passage of air should also be considered if the fabric is intended for use in a wind-resistant garment. The A.A.T.C.C. spray and immersion tests are well suited for evaluating (1), and the hydrostatic pressure and impact penetration testers for (2) and (3). It is believed that the hydrostatic pressure test and the impact penetration test could be used together to grade water-resistant fabrics intended for use in rain wear, and a suitable grading system is suggested. C.

**Rayon Fabrics: Finishing; Softness Test.** See Section 4H.

**Filtering Fabrics: Stability** O. R. Herfurth. *Deut. Wollen-Gewerbe*, 1942, 74, 461-466 (through *Chem. Zentr.*, 1942, ii, 2065 and *Chem. Abstr.*, 1944, 38, 2237<sup>4</sup>). A discussion of the action of water, acids and alkalis on the filtering medium, dry filtration, filtration temperature, and the nature of the weave and thickness of the fabric. The mechanical stress caused by the filtering pressure is discussed. None of the various impregnations tried has made it possible to produce a good, long-lasting filtering medium from staple fibre for wet filtration. The use of Pe-Ce fibre and of nylon is described. Natural fibres, but not synthetic fibres, are resistant to mechanical stress; this is probably due to the fact that the natural products are protected partly by incrustations. C.

**Formaldehyde: Determination in Formalin-treated Fabrics.** G. zum Tobel and F. Vogel. *Zellwolle, Kunstseide, Seide*, 1941, 46, 59-61 (through *Chem. Zentr.*, 1941, ii, 3316 and *Chem. Abstr.*, 1944, 38, 2503<sup>1</sup>). Formaldehyde was determined by decomposing a sample with hydrochloric acid and precipitating it from the steam distillate with 5:5-dimethyldihydroresorcinol. Fabrics treated commercially with formalin contained 0.15-0.74 per cent. of formaldehyde. The reaction of these fabrics with various chemicals indicated that most of the formaldehyde was combined with the fibre chemically. In fabrics treated with

urea-formaldehyde resins there was no chemical union between the fabric and the formaldehyde. C.

**Nylon Fabric Weaving Defects: Causes and Correction.** R. E. Spear. *Textile World*, 1944, 94, No. 5, 101. Illustrations are given of weft defects due to (1) oil stains, (2) snarling, and (3) slack picks due to a rebounding shuttle, with hints on the correction of the trouble. C.

**Spun Rayon Fabrics: Quality.** H. Böhlinger and W. Graf. *Textilberichte*, 1943, 24, 347-357 (through *Chem. Abstr.*, 1944, 38, 2500<sup>2</sup>). A true comparison of the quality of fibres of different specific gravity is possible only for those textile structures containing the same weight of dry substance. Physical tests are described and discussed. C.

#### (D)—OTHER MATERIALS

**Paper Bursting Strength Tester.** Technical Association of the Pulp and Paper Industry. *Paper Trade J.*, 1944, 118, *TAPPI*, 159-160. A revision of TAPPI standard T403m-41, giving specifications of a bursting strength test and instrument for papers up to 0.025 in. thick. C.

**Paper Stretch Testing Machines: Comparison.** Institute of Paper Chemistry. *Paper Trade J.*, 1944, 118, No. 26, 12-16; 119, No. 1, 24-30; No. 2, 24-30. A critical discussion is offered of the measurement of stretch in paper by means of (1) the Amthor universal tensile strength tester, (2) the Clark stretch tester, (3) the Schopper electrically-driven strength tester and (4) the Scott serigraph. The calibration of the machines is also considered. Defects of design are brought to light. The stretch of paper is found to decrease with increasing specimen length but to be virtually independent of width or of the rate of loading. C.

**Nitrocellulose Films: Plasticity.** Madeleine Raison and M. Marcal. *C. r. Acad. Sci.*, 1941, 212, 157-159 (through *Chem. Zentr.*, 1941, ii, 3226 and *Chem. Abstr.*, 1944, 38, 2199<sup>8</sup>). For experiments on the extension of nitrocellulose, small ribbons were used, 5 cm. long, 4 mm. wide and 0.04-0.07 mm. thick. They were kept in a tube which contained solvent. The extension curves always show the same form. There is a flat ascending portion (*H*) which corresponds to the elastic range, followed by a steeper portion which is ascribed to the plastic range (*P*). At higher concentrations of a softening agent in the solution, *H* is shortened, whereas the angle of inclination of *P* remains unchanged. With increasing amounts of the softening agent taken up, the curve increases in steepness, and coincides with the ordinate axis when the ratio of softening agent to  $C_6$  group reaches unity. The elasticity is then zero and the plasticity is complete. Whereas hexane and cyclohexane, used as solvents for the softening agent, do not change the mechanical properties of the films, films of nitrocellulose are plasticized by benzene. The portion *H* is almost non-existent, and portion *P* almost vertical, proving that benzene acts, in this system, as a plasticizer. C.

**Pulp: Viscosity Test in Cupriethylenediamine Solvent.** E. P. Wood. *Paper Trade J.*, 1944, 118, *TAPPI*, 169. The writer advocates a modification (not described) of Straus and Levy's viscosity test for pulps, using cupriethylenediamine solvent, on the score that it is quicker than the cuprammonium method, a single test requiring only 20 minutes. C.

**Sulphite Pulps: Viscosity; Comparison of Cuprammonium and Cupriethylenediamine Measurements.** A. J. Corey. *Paper Trade J.*, 1944, 118, *TAPPI*, 167-168. The author records the viscosities of 1 per cent. solutions of eleven samples of bleached sulphite pulp in cuprammonium and cupriethylenediamine as solvents. The respective values range from 10.5 to 85.5 cp. for the first solvent and 16.2 to 440 cp. for the second, and fall on a curve that is slightly concave towards the axis used for the cupriethylenediamine values. Four to eight measurements were made on each sample and a greater degree of uniformity was obtained when using the second solvent. C.

**Bacteria: Collection from Air and Textiles.** H. M. Lemon. *Proc. Soc. Exp. Biol. and Med.*, 1943, 54, 298-301 (through *Biol. Abs.*, 1944, F, 18, 6939). Air is dispersed at 30 l. per min. through a Folin aeration tube into 20 ml. broth and 2-3 drops olive oil contained in a 200 × 32 mm. test tube. Loss of fluid is prevented by exhausting the air through a Kjeldahl trap (square glass baffle) inserted into the same stopper that holds the Folin tube. Comparison with the

Moulton atomizer sampler in 26 tests with air of inhabited rooms and air infected with  $\beta$ -hemolytic streptococcus Group C, dispersed as fine droplets, showed this device to be 90 per cent. efficient. The number and type of bacteria on textiles can also be estimated by attaching a glass funnel to the intake of the sampler and drawing 30-60 l. of air through sheets or blankets. W.

#### PATENT

**Fabric Measuring Machine.** M. P. Oliver and W. T. Oliver. B.P.562,623 of 12/1/1943:10/7/1944. In a fabric measuring machine of the type in which the fabric is pulled between a measuring roller and a pressure roller, the pressure roller is mounted in a bracket secured to a rotatable shaft, the bracket being subjected to the action of a spring normally tending to press the roller towards the measuring roller, and the bracket being provided with a roller co-operating with a cam carried by a sliding frame normally urged in a direction to move the cam under the roller so as to hold the pressure roller in its inoperative position. C.

### 7—LAUNDERING AND DRY-CLEANING

#### (A)—CLEANING

**Alkylaminoethanol Invert Soaps: Preparation.** P. Rumpf and P. Kwass. *Bull. Soc. Chim.*, 1943, 10, 347-349 (through *Chem. Abstr.*, 1944, 38, 2317<sup>a</sup>). The preparation and properties of the following derivatives of aminoethanol are described: dibenzyl-, benzyl-, dihexyl-, hexyl-, didodecyl-, dodecyl-, and hexadecyl-. Their salts do not foam but are remarkable for emulsifying power. The hydrochlorides of the mono-derivatives are excellent sources of invert soaps. C.

**Double Invert Soaps: Preparation.** J. B. Niederl and E. J. Kenney. *J. Amer. Chem. Soc.*, 1944, 66, 840-841. Methylene- and benzal-di-morpholine have been condensed with a variety of alkyl bromides, such as *n*-butyl, *n*-heptyl, *n*-octyl, tetradecyl and hexadecyl bromides, to yield the corresponding symmetrical di-morpholinium di-bromides. C.

**Soap and Synthetic Detergent Mixtures: Analysis.** D. Berkowitz and R. Bernstein. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 239-241. A procedure for the analysis of mixtures of soap and synthetic detergents in bar form is described in which the sample is extracted with 95 per cent. ethyl alcohol to remove the major portion of the active ingredients and the residue is dissolved in the smallest possible quantity of water and reprecipitated by the addition of ethyl alcohol in order to free it from adsorbed detergent. Soap, fatty matter, and alcohol-soluble chlorides are determined directly and synthetic detergent is determined as the difference between total alcohol-soluble matter and the sum of soap, fatty matter, and alcohol soluble chlorides. Results obtained on known mixtures are of satisfactory accuracy and reproducibility. C.

**Textile Materials: Effect of Washing.** H. Opitz. *Mikrokosmos*, 1941, 34, 153-156 (through *Chem. Zentr.*, 1941, ii, 3014 and *Chem. Abstr.*, 1944, 38, 2502<sup>a</sup>). Microscopic observations have been made of the effects of washing on cotton, flax and viscose staple fibre. Commercial washing operations were carried out with completely softened water, a soda bath, washing for 10 min. in soap solution at 80°, after-treating in a Calgon bath, rinsing in warm, soft and in cold, hard water and centrifuging. The textiles were tested after 25, 50 and 100 such washings. The damage was greatest for the spun rayon, less for bast fibres and least for the cotton. Deposits, particularly of calcium soaps are harmful. These soaps are detected with alizarin solution. Photomicrographs are given in the original. C.

**Washing Compounds: Photometric Measurement of Detergent Power.** J. I. Wilson and E. E. Mendenhall. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 251-254. The calcium and magnesium salts present in hard water react with many detergents to form insoluble compounds. Some of the precipitate thus formed attaches itself to objects being washed and in some processes, such as commercial dish-washing, builds up an unsightly film. A simple photometer has been designed for measurements on such films. The transmission of light by test plates, comprising squares of plate glass is measured, before and after washing, by means of a photocell and a measuring circuit of relaxation oscillator type which causes a series of clicks to be heard in a high-impedance telephone. Results are expressed as visual thickness of film. The use of this instrument

for the determination of the rate of film formation in the washing of glass objects with different detergents is described. Curves are given showing visual thickness of films against number of wash cycles. Of the three alkaline materials, most commonly found in commercial dish-washing detergents, trisodium phosphate produced the least film during 10 repeated washing cycles. Sodium metasilicate produced a heavier film than trisodium phosphate under the test conditions, but less film than soda ash. A proprietary compound containing 25 per cent. tetrasodium pyrophosphate, 40 per cent. sodium metasilicate, and 35 per cent. soda ash produced after 10 cycles a film having a visual thickness of only 15 units as compared with 31 units for trisodium phosphate alone. A proprietary compound containing 32 per cent. of sodium tetraphosphate ( $\text{Na}_6\text{P}_4\text{O}_{13}$ ), 40 per cent. sodium metasilicate pentahydrate, and 28 per cent. of sodium carbonate gave a film of visual thickness less than 2 units. C.

#### PATENT

**Washing Machine Oscillating Mechanism.** British Thomson-Houston Co. Ltd. B.P. 563,020 of 28/12/1942:26/7/1944 (Conv. 31/12/1941). A variable-stroke oscillating mechanism for washing machines comprises a segment gear and a pinion, means for oscillating the segment gear about an axis, means for adjusting the axis of the segment gear toward and away from the pinion, and co-operating friction surfaces on the pinion and segment gear, the friction surface on the segment gear having a part on one side of an arc passing through its ends concentric with the axis of oscillation, whereby the length of friction contact between the segment and the pinion varies with the adjustment of the axis of the segment. C.

### 8—BUILDING AND ENGINEERING

#### (A)—CONSTRUCTION AND MAINTENANCE OF BUILDINGS AND PLANT

**American Textile Machinery: Developments.** N. M. Mitchell. *Textile Manufacturer*, 1944, 70, 301-303. A useful list is given of new developments in spinning, winding, weaving, dyeing and finishing machinery, arranged in alphabetical order of the machinists' names. C.

**Cellulose Acetate Plastics: Moulding.** W. O. Bracken and F. E. Piech. *Ind. Eng. Chem.*, 1944, 36, 452-456. Strain patterns shown by translucent cellulose acetate injection-moulded plastics in polarized light have been studied and related to variations in temperature, pressure and other conditions of moulding. The results indicate that injection temperatures of cellulose acetate plastics should be sufficiently high to obtain homogeneity in mouldings. Lower temperatures result in poor fusion and a high degree of strain. High-acetyl (57 per cent. combined acetic acid) cellulose acetate injection plastics require high temperature, high pressure, and low rate of filling of the mould to produce heavy-sectioned pieces having minimum impressed strain. High temperature and pressure are necessary to obtain closest mould reproduction. Low rate of filling of the mould aids in forming bubble-free pieces. Cellulose acetate plastics of the P.M. type (53 per cent. combined acetic acid) generally require higher injection pressures than plastics of higher acetyl content to avoid bubble formation in thick pieces. Side gating is more effective than corner gating in producing pieces relatively free from strain. There are minimum pressures below which bubble formation consistently occurs in heavy mouldings. Increased mould temperatures and longer periods in warm moulds improve the strain structure of plastics. In the production of cellulose acetate sheet stock the following conditions give products with minimum strain: solvent content prior to baking about 17 per cent., baking temperature approximately 320° F., and cooling pressure 500-1,000 lb. per sq. in. C.

**Laminated Paper Plastics: Effects of Moisture Content on Physical Properties.** A. H. Croup. *Paper Trade J.*, 1944, 118, TAPPI, 175-178. Sheets of sulphite pulp paper were impregnated with an alcoholic solution of phenol-formaldehyde resin, conditioned at 9, 22, 32.5, 52.5, 64, 81 and 94.5 per cent. R.H., and made into laminated panels  $\frac{1}{8}$ -in. thick by compression for 12 minutes under 250 lb. per sq. in. at 160° C. About 60 sheets were required. The panels were then conditioned at 52 per cent. R.H. and 22° C. and submitted to various physical tests. The following data are tabulated and plotted against the per cent. R.H. at which the impregnated paper was conditioned: (1) total volatile matter (loss at 160° C.) and (2) moisture content, at the time of laminating;

and, for the laminate, (3) specific gravity, (4) moisture regain, (5) increase in thickness due to moisture absorption, (6) tensile strength, (7) modulus of elasticity, (8) modulus of rupture under flexing, (9) modulus of elasticity under flexing, (10) edge impact strength (Izod), and (11) resistance to abrasion. Test conditions are recorded. The results show that as the moisture content of the sheets increased the tensile and flexing strengths of the laminates decreased, the moisture absorption increased, dimensional stability became poorer, impact strength was slightly increased, and specific gravity and resistance to abrasion were not affected. It appears, therefore, that the moisture content of the impregnated paper should be controlled if strength and uniformity of the laminate are important consideration. In a second part of the investigation, panels made from three sorts of paper at the same regain were themselves conditioned at the above range of humidities, and also soaked in water, and tested for regain, tensile and impact strengths, and resistance to abrasion. The data are plotted against per cent. R.H. and the trends are discussed. It was subsequently realised, however, that laminated panels do not reach moisture equilibrium with the conditioning atmosphere in less than 3 months, whereas only 48 hours was allowed in these experiments. C.

**Phenol Paper Laminates: Development.** G. K. Dickerman. *Paper Trade J.*, 1944, 118, *TAPPI*, 239-242. The writer discusses the development of strong phenolic paper laminates for aircraft construction and gives data about the engineering properties of recent products. The need for specifications of the paper is pointed out. C.

**Air Compressors.** D. Braid. *Mech. World*, 1944, 115, 285-9, 371-8. In the erection of a compressor and its prime mover the important points to watch are the foundations, the setting of the bedplate, and the aligning of bearings and shafts. The procedure and points to watch in starting up a new installation or after an overhaul are considered in some detail. La.

**Pipe Joints.** G. W. McArd. *Mech. World*, 1944, 115, 382-3, 391-3. Joints and jointing materials are discussed under the headings joint tightness, design and machining, jointing material, jointing pressure, and fluids. A table shows recommendations of three manufacturers for materials for use with different fluids. La.

**Electric Welding Plant.** G. W. Stubbings. *Mech. World*, 1944, 116, 123-4. A brief consideration of load factor with particular reference to supplies for electric welding plant and the principle of static equipment for balancing a single phase load on a 3-phase system. La.

**Wood in Modern Construction.** G. W. McArd. *Mech. World*, 1944, 116, 227-32. The supply and properties of various woods are first considered and the latest developments in bonded plywood, moulded plywood and combinations of asbestos board and plywood are illustrated and described. La.

**Lubricating Appliances.** E. V. Paterson. *Mech. World*, 1944, 116, 255-60. Present day lubricating equipment is illustrated and described. Included are simple oilers, wick feeds, drop oilers and mechanical lubricators. La.

**Heat Exchange.** C. H. Fielding. *Power & Works Engineer*, 1944, 39, 80-2, 108-11. Among the many factors encountered in heat transfer problems is the way in which the physical proportions affect the heat exchange. These articles are particularly concerned with surface and volume and the relation between heat transfer and surface/volume is examined for pipes, condenser tubes, heat exchangers, fine wires. La.

**Reducing Factory Noise.** *Mech. World*, 1943, 114, 763. Notes on the use of sound absorbing materials based on a recent American paper. La.

**Industrial Chromium Plating.** *Power & Works Engineer*, 1944, 39, 187. A discussion of why and how chromium plating is employed in numerous cases in machine tool and other engineering fields. La.

**Safety in Process Equipment.** *Power & Works Engineer*, 1944, 39, 10-11. Notes on Hazards associated with process apparatus, with special reference to explosion in direct fired furnaces. La.

**An Aquatherm Installation.** *Power & Works Engineer*, 1944, 39, 29-31. A description of some of the engineering services at the factory of the Empire

Rubber Co., including a very satisfactory high-pressure water circulating system for process purposes. La.

**Compressor Economies.** "Pneumatic." *Power & Works Engineer*, 1944, 39, 36, 38. Notes on simple and practical methods of improving the production of compressed air. La.

**Engineering Fundamentals 22.** *Power & Works Engineer*, 1944, 39, 112-3. Some alternating current appliances are considered. La.

**Models.** *Power & Works Engineer*, 1944, 39, 164. Models are extremely useful in engineering and chemical engineering and they are here discussed under the headings: materials, model makers, plastics, the cost aspect. La.

**Practical Pointers.** J. G. Berger. *Starchroom Ldy. J.*, 1944, May, 88. Twelve suggestions to help to keep plant running under difficult maintenance conditions. They include a soot remover, locating cracks in metal plant, making a tight joint and so on. La.

**Power Plant Notes.** W. F. Schaphorst. *Starchroom Ldy. J.*, 1944, May, 96-9. Notes on starting a new boiler, in lieu of rubber, test lubricants and bearings, burning air, belts on flanged pulleys, steam leaks, safety valves. La.

**Earthing Electrical Plant.** G. W. Stubbings. *Power & Works Engineer*, 1944, 39, 175-6. The reasons for earthing the frames of motors and other equipment are explained and the necessity for regular inspection and testing of earth continuity connections is stressed, with particular reference to factory conditions. La.

#### (C)—STEAM RAISING AND POWER SUPPLY

**Chatter in Safety Valves.** G. H. Pearson. *Mech. World*, 1944, 115, 575-6. There is less proneness to chatter in the case of safety and other controlled lift valves if the point of thrust of the valve spindle is situated at some distance below the contacting faces of the valve members. La.

**The Mol in Combustion Calculations.** J. Jennings. *Mech. World*, 1944, 115, 627-8. The "mol" is the quantity of matter whose weight is equal to its molecular weight in pounds and it is an exceedingly useful unit in combustion calculations. Examples are given for the combustion of acetylene and a flue gas analysis. La.

**Boiler Feed Systems.** H. Hillier. *Mech. World*, 1944, 116, 125, 132-7, 163-5, 188-92, 208-9. In an abstract of a paper on "Boiler Feed Water Regulation" (presented to Institute of Marine Engineers) feed system characteristics are first analysed. A number of feed installations and control devices are illustrated and described. La.

**Overload Trips for Electric Motors.** G. W. Stubbings. *Mech. World*, 1944, 116, 206-7. The basic characteristics of thermal overload trips for electric motors are considered and from these are developed two practical rules for operation. La.

**Steam Pipe Insulation.** H. Buckley. *Mech. World*, 1943, 114, 753-6, 778-9. After considering the heat loss theoretically, including the values of constants for various materials, the economic aspect is discussed, and a method is evolved for finding the economic thickness. General characteristics of insulating materials, their choice, fixing and finishing are also briefly considered. La.

**Installation and Care of Electric Motors.** Engineer-in-Charge. *Mech. World*, 1944, 115, 171-5. The type of motor must be suited to the working conditions and the maintenance must be suited to the requirements for efficient performance of the type chosen. The subject is considered under the headings: conditions and type, starting and cables, drive, maintenance of bearings, loading and connections, collecting gear and insulation tests. La.

**Boiler Fittings.** G. H. Pearson. *Mech. World*, 1944, 115, 199-202, 249-51, 274-7, 303-7, 331-5. An interpretation of B.S. 759-1937 dealing with valves, gauges and similar fittings for land boiler installations. The specification is considered in detail and many diagrams are included to illustrate various points. La.

**Process Steam and Power.** H. M. Peacock. *Power & Works Engineer*, 1944, 39, 5-8, 32-4, 57-8, 89-92, 104-6. A comprehensive treatment of the whole subject of generating power in establishments using steam for press or heating. In

general the exhaust steam is used for process at pressures ranging from 10-100 p.s.i. and for normal factories the boiler pressure should be at least 150 p.s.i. to make "back-pressure" power generation worthwhile. "Pass out" sets are used when the power required would yield more exhaust steam than could be absorbed by process. Comparison between power station and local generation is made by means of Sankey diagrams and illustrative cost figures, and the advantages of back-pressure generating plant are clearly shown. A table shows the horsepower to be expected from a variety of reciprocating engines and turbines and consideration is then given to the theoretical aspect starting with the Rankine diagram and Willans line. The working pressures are considered in some detail and the desirability of avoiding reducing valves is stressed. Whenever the exhaust steam is insufficient for or balances the process requirements care should be taken to introduce the maximum heat economy or to ensure an hour to hour balance as well as a weekly or daily balance. A number of ways of using excess exhaust steam are considered including the purchase of electric power, the installation of a heat accumulator or exhaust turbine. A final section describes the use of the Mollier diagram in power plant problems.

La.

**Engineering Fundamentals 18.** *Power & Works Engineer*, 1944, 39, 18-19. Notes on the direct current dynamo.

La.

**Engineering Fundamentals 19.** *Power & Works Engineer*, 1944, 39, 39-40. The direct-current motor.

La.

**Steam and Power Balancing.** H. M. Peacock. *Power & Works Engineer*, 1944, 39, 125-7. Methods of improving the balance between steam loads and power demand in factories employing combined power-process steam systems are briefly discussed.

La.

**Economiser Performance.** R. H. Parsons. *Power & Works Engineer*, 1944, 39, 129. An alignment chart is given and described enabling economiser heat transmission to be estimated from the two temperature differences (i.e. gas inlet, water inlet) and the water-flow per sq. ft. of heating surface. Any deterioration in efficiency is readily found.

La.

**Outcrop and Opencast Coal.** J. N. Williams. *Power & Works Engineer*, 1944, 39, 135-6. The general characteristics of these coals are first discussed briefly and then the firing technique is considered. In general side firing is to be preferred, but proper fire cleaning is essential.

La.

**Energy Cost for A.C. Motors.** G. W. Stubbings. *Mech. World*, 1944, 115, 718-9. A note on balancing the cost of complication against the effect of a gain in power factor.

La.

**Power Rectifier.** J. Tyler. *Power & Works Engineer*, 1944, 39, 153-4. A survey of the types of power rectifier available commercially for heavy work, including a review of progress and an estimation of the probable trend.

La.

**Surface Condensers.** W. Miles. *Power & Works Engineer*, 1944, 39, 158-9. A brief consideration of surface condensers, including a condenser performance chart.

La.

**Calorific Value.** R. H. Parsons. *Power & Works Engineer*, 1944, 39, 163. A diagram which enables an estimate of the calorific value to be made from the proximate analysis is illustrated and described.

La.

**Power from Process Steam.** R. Hammond. *Steam Engineer*, 1944, 13, 326-331. The first of a series of articles describing different types of plant designed to make the maximum use of the heat in steam for power and process purposes. This article describes a Sulzer compound (tandem) engine and plant working with steam extraction.

La.

**Coke Breeze and Pitch.** *Steam Engineer*, 1944, 13, 347-8. A brief account of experiments carried out by the Chemical Engineering and Wilton's Patent Furnace Co. Ltd. to examine the conditions under which coke breeze and pitch can be burnt on boiler furnaces. A special trough for mixing the pitch and coke breeze is illustrated diagrammatically the mixture consisting of about 15 per cent. of pitch by weight. An increase in efficiency over coke breeze used alone was obtained, the evaporation from and at 212° F. rising from 5.52 to 6.07 lb. of water per lb. of fuel.

La.

**Changing from D.C. to A.C.** *Power & Works Engineer*, 1944, 39, 178-9, 182. A factory engineer records his experience while changing a factory from D.C. to A.C. La.

**New Economisers.** W. Goldstern. *Steam Engineer*, 1944, 13, 134-8. Some notes on the selection of a new economiser for an industrial installation. La.

**Dust, Soot and Efficiency.** W. Goldstern. *Steam Engineer*, 1944, 13, 167-70. The effect of flue dust and soot deposit on the efficiency of Lancashire boilers is examined by considering actual figures for boiler house data from textile mills. La.

**Boiler Efficiency.** H. L. Pirie. *Steam Engineer*, 1944, 13, 199-203. Practical notes on boiler efficiency include illustrations and descriptions of an air excluder for a side flue damper of a Lancashire boiler, critical positions of dampers, path of gases with and without baffles, a flue striking pillar and Bower baffles. Several general points are also briefly considered. La.

**Safety Valves.** E. Ingham. *Steam Engineer*, 1944, 13, 249-51. A common type of high steam and low-water safety valve is illustrated and the correct procedure for ensuring its efficient operation is described. La.

**Extraction Steam from a Corliss Engine.** S. Bentley. *Steam Engineer*, 1944, 13, 264-8, 263. Some notes on an interesting extraction system applied to an existing Corliss engine at a Yorkshire woollen mill. La.

**Uniflow Engine.** *Steam Engineer*, 1944, 13, 365-8. Some notes on an installation in a hosiery plant, including a small water tube boiler and a uniflow engine providing exhaust process steam. La.

**Combustion in Shell-type Boilers.** E. E. Burrage. *Steam Engineer*, 1944, 13, Supplement (Sept.). Coloured diagrams illustrate furnace and chimney top conditions for a shell-type boiler fitted with a sprinkler stoker. Five states of the fire are shown with relevant descriptive information, including per cent. CO<sub>2</sub>, excess air and heat loss. La.

**Industrial Heat Insulation.** W. Francis. *Power & Works Engineer*, 1944, 39, 149-52, 183-6, 204-7. A straightforward explanation of the economics of thermal insulation with particular reference to factory steam and hot-water services. The first section considers heat loss theoretically and tables of constants for various insulating media are given. The economics of the system are next considered by plotting first the heat savings and the annual cost of the lagging and combining these to give a total cost curve. This curve has a minimum at the most economical thickness. Certain practical aspects, e.g. resistance to moisture, cost of application, are then discussed. Finally the properties of commercial types of lagging and some miscellaneous applications are described. La.

**"Reflex-Ordinate" Boiler Efficiency Diagram.** H. C. Golder and R. B. Page. *Power & Works Engineer*, 1944, 39, 40, 56. This diagram allows the efficiency of a boiler to be estimated by means of a series of points and lines. The order in which the components are used is steam temperature, gauge pressure, feed temperature, calorific value of fuel, actual evaporation and efficiency. The low range chart covers steam temperatures from 290°-600° F. and pressures from 50-250 p.s.i.g., while the higher range chart covers temperatures from 500°-800° F. and pressures from 100-500 p.s.i.g. Larger scale charts can be obtained. La.

**Cast-iron Heating Boilers.** J. Evens. *Power & Works Engineer*, 1944, 39, 41-2. A brief discussion of some of the causes that lead to cracking and breakdown of cast-iron sectional and other heating boilers, together with suggestions for their avoidance. La.

**Economisers and Air Preheaters.** W. Wadkin. *Power & Works Engineer*, 1944, 39, 44-6. Factors controlling the relative sizes of economisers and air preheaters in modern boiler plant are considered. La.

**Fuel Characteristics and Boiler Efficiency.** R. Rowatt. *Power & Works Engineer*, 1944, 39, 60-2. A general discussion on the effect of coal characteristics on combustion efficiency, with suggestions for improving existing and maintaining better boiler house operation. La.

**High-speed Electric Drives.** G. W. Stubbings. *Power & Works Engineer*, 1944, 39, 63-4. The method of operation of the induction frequency-changer is explained as it is the normal modern equipment used to secure higher frequency supplies for high-speed electric drives of hand tools, wood-working machines, etc. La.

**Elementary Lagging.** *Power & Works Engineer*, 1944, 39, 64-5.

**Engineering Fundamentals 20.** *Power & Works Engineer*, 1944, 39, 66-7. A brief account of alternating currents and their behaviour in circuits having inductance and capacitance. La.

**Engineering Fundamentals 21.** *Power & Works Engineer*, 1944, 39, 83-4. Further considerations relating to alternating currents and their practical implications. La.

**Boiler Operation.** C. H. Fielding. *Power & Works Engineer*, 1944, 39, 197-8, 208. Diagrams giving a useful picture of the variable factors involved in practical boiler operation can be prepared from easily available data. Examples are illustrated and described with special reference to chain-grate fired water tube units. La.

**Lubrication of Gears and Gearboxes.** E. V. Paterson. *Mech. World*, 1944, 115, 505-6, 532-5, 561-2. Dissipation of heat is the most important function of oil in gear boxes and in order to obtain the most satisfactory results certain points must be watched. The sources of friction are between the meshed teeth, the oil itself and the churning of the oil. The first demands a high viscosity oil and the last two a low one so that a compromise has to be made. The required viscosity and other properties of suitable lubricants are briefly considered. Typical gearboxes and methods of applying the oil, e.g. pressure feed, spray lubrication are illustrated and described. La.

**Lubrication of Plain Bearings.** E. V. Paterson. *Mech. World*, 1944, 116, 199-203. The basic principles are discussed and applied to the grooving of bearings. The distribution of pressure in an oil film, clearances, effect of surface finish, effect of shaft distortion, correct point of introducing oil, dangers of oil grooves, force feed systems and similar points are briefly considered. La.

**Ball and Roller Bearings.** R. K. Allan. *Mech. World*, 1944, 115, 149-52. Ball and roller bearings give long and efficient service if they are of the correct size and type and due care is exercised in their handling, fitting and maintenance. Drawings and instructions should be studied before fitting or dismantling to find what tools are required. Handling, fitting, lubrication, sealing, maintenance, unsatisfactory running, dismantling, repairing and cleaning are also considered. La.

**Metallic Packing.** R. W. McArd. *Power & Works Engineer*, 1944, 39, 155-8. The value of metallic packing for sealing reciprocating rods and revolving shafts is discussed and several examples are illustrated and described. La.

**Centrifugal Compressors.** W. J. Roberts. *Power & Works Engineer*, 1944, 39, 77-9. An outline of the principles and plant employed for the control and regulation of air compressors. La.

**Power Transmission.** E. L. Cady. *Ldy Age*, 1944, June, 57-8, 60, 62, 64. One of the most important factors in power transmission maintenance is alignment. Causes of wear and types of misalignment are illustrated and discussed and methods of ensuring correct alignment of shafts, pulleys and motors are described. La.

**Lubrication of Plain Bearings.** E. V. Paterson. *Mech. World*, 1944, 116, 314-6. Methods of applying grease for the lubrication of plain bearings are illustrated and described. La.

#### (D)—POWER TRANSMISSION

**Lubricating Oils: Oxidation.** G. H. Denison, Jr. *Ind. Eng. Chem.*, 1944, 36, 477-482. Refined lubricating oils consist of hydrocarbons, together with 2-20 per cent. sulphur compounds, 0.08-0.3 per cent. nitrogen compounds and some oxygen compounds. The hydrocarbon fraction is a mixture of naphthenes with homologues of benzene and naphthalene. When the natural sulphur compounds are removed without appreciably affecting other constituents, the hydrocarbon fraction shows negligible resistance to oxidation. The stability of

lubricating oils thus appears to depend on the presence of the natural sulphur compounds. Studies of the mechanism of oxidation of a sulphur-free oil and observations of the rate of peroxide decay when blends of a finished lubricating oil with a sulphur content of 0.53 per cent. and a peroxide-rich pre-oxidised white oil are heated in the absence of air show that the hydrocarbon fraction oxidises at a rate controlled by the concentration of organic peroxides, and that the latter are reduced by reaction with inhibitors that contain sulphur. Further experiments show that, in addition to controlling the rate of oxidation of an oil, the organic peroxides determine the rate of corrosion of bearing metals. The corrosion results from the ability of peroxides to convert metal into metal oxide, the latter subsequently dissolving by reaction with acidic constituents developed during oxidation. C.

**Motor Starters: Maintenance.** J. Z. Linsenmeyer and L. E. Markle. *Textile World*, 1944, 94, No. 4, 98-101, 180. Practical advice is given on the care, testing and maintenance of motor starters. The hints are summarised in a table in which the headings are (1) nature of the trouble, (2) cause and (3) what to do. C.

**Chain Drives: Maintenance.** Chain Belt Co. *Textile World*, 1944, 94, No. 5, 134. A table is given of symptoms of bad running of driving chains, with possible causes and remedies. C.

#### (F)—LIGHTING

**Textile Mills: Lighting.** *Textile World*, 1944, 94, No. 4, 104-105. Many textile processes require good general illumination supplemented by effective local lighting. The following intensities (foot-candles) are recommended:

	General	Local		General	Local
Storage ... ..	5-10	—	Drawing-in ... ..	25-30	100-200
Opening and scutching ...	10-20	—	Full-fashioned knitting ..	35-40	—
Carding ... ..	10-20	—	Circular knitting ... ..	35-40	—
Roving ... ..	35-40	—	Looping ... ..	35-40	100-200
Spinning (ring) ... ..	35-40	—	Seaming ... ..	35-40	100-200
Twisting ... ..	35-40	—	Cloth inspection ... ..	30-35	100-200
Mule spinning ... ..	50-55	—	Knit goods inspection ...	30-35	100-200
Throwing ... ..	30-35	—	Narrow fabrics inspection	30-35	150-250
Winding ... ..	30-35	—	Printing ... ..	30-35	75-150
Sizing ... ..	25-30	100	Perching ... ..	30-35	100-250
Warping ... ..	30-35	100-150	Shading ... ..	30-35	100-150
Weaving ... ..	25-50	100	Machine shop ... ..	25-30	100-300

C.

**Workshop Lighting.** *Mech. World*, 1944, 115, 419-21. Notes on a memorandum on "Workshop Lighting and Production Efficiency," issued by the E.L.M.A. Lighting Service Bureau. La.

#### (G)—HEATING, VENTILATION AND HUMIDIFICATION

**Electronic Control Equipment: Maintenance.** W. D. Cockrell. *Textile World*, 1944, 94, No. 5, 82-83. Practical hints are given on the supervision of electronic control equipment, including the location of defects. C.

**Temperature Drop in Ducts.** A. B. Kratz, S. Konzo and R. B. Engdahl. *Mech. World*, 1944, 116, 264-5. An abstract of Bulletin No. 351 (University of Illinois) giving data for the calculation of the drop in temperature of heated air conveyed in galvanised-iron ducts of round, square and rectangular section, uninsulated and in a horizontal position. La.

#### (H)—WATER PURIFICATION

**Mechanical Filtration of Water.** J. J. Dillwyn. *Mech. World*, 1944, 115, 433-7. An abstract of a paper read before the Manchester Association of Engineers. Equipment is illustrated and described for filtration by the slow sand, rapid gravity and pressure processes. La.

**Water for Industrial Use.** J. Brittain. *Mech. World*, 1944, 115, 1-3. The preliminary treatment of water for industrial purposes includes the removal of debris. Suitable screens, strainers, and so on, are briefly described. La.

**Water Supply.** J. G. Berger. *Starchroom Ldy J.*, 1944, June 15, 94, 96, 105, 106. The economics of using town or well water are discussed and the advantages

of softening to zero hardness are emphasised by examples of savings so produced in ten different localities. La.

**Submersible Pump.** *Power & Works Engineer*, 1944, 39, 211-3. An illustrated description of a big wet-motor submersible pump recently supplied by Hayward-Tyler & Co. Ltd. for dewatering a colliery shaft. The motor is rated at 350 b.h.p. and will absorb 290 b.h.p. while raising 700 g.p.m. against a total head of 1,030 ft. La.

## 9—PURE SCIENCE

**Electron Tubes: Principles and Characteristics.** A. W. Kramer. *Instruments*, 1944, 17, 206-209, 224-228. The principles and characteristics of the tetrode and pentode are described, and modern X-ray and cathode-ray tubes are briefly discussed. C.

**Lanosterol.** C. Dorée and J. F. McGhie. *Nature*, 1944, 154, 147-148. Recent evidence indicates that lanosterol is probably connected with the tri-cyclic terpenes, e.g.  $\alpha$ -elemolic acid and with cryptosterol. A series of yellow ketonic products has been isolated by oxidising lanosterol and its esters with ozone and with chromic acid. These derivatives include a diketo-alcohol,  $C_{30}H_{46}O_3$  (m.p. 145°), the corresponding triketone,  $C_{30}H_{44}O_3$  (m.p. 110°), and a compound  $C_{27}H_{40}O_4$  (m.p. 203°), of which an account will shortly be published. W.

**Analysis of Hair Keratin. (2) Dicarboxylic and Basic Amino-acids of Human Hair.** J. M. R. Beveridge and C. C. Lucas. *Biochem. J.*, 1944, 38, 88-95. The influence of the order of separation of the amino-acids from a human hair hydrolysate upon their quantitative isolation has been investigated. A suitable order of separation of the dicarboxylic and dibasic amino-acids is reported. Aspartic acid (3.5 per cent.) has been isolated for the first time from human hair. Glutamic acid has been isolated in higher yields than previously reported. The quantities of basic amino-acids isolated agree essentially with those reported in the literature. The unexpected finding of methionine in a fraction derived from a washed and reprecipitated cuprous mercaptide precipitate casts some doubt upon the universal applicability of the method of estimating cystine by the organic sulphur content of this precipitate. W.

**Analysis of Hair Keratin. (3) Isolation of Proline from Human Hair.** J. M. R. Beveridge and C. C. Lucas. *Biochem. J.*, 1944, 38, 95-97. Conditions for the quantitative isolation of proline, suitable for use in a systematic scheme of separation of amino-acids from hydrolyzed hair keratin, have been studied. Maximum yield of proline (4.3 per cent.) was obtained by application of Town's copper salt method, after preliminary removal of cystine, arginine, most of the tyrosine, the dicarboxylic acids, histidine, lysine and some leucine. No hydroxyproline could be found in human hair hydrolysates. W.

**Action of Sulphites on the Cystine Disulphite Linkages of Wool. (4) Methylation of the Thiol Groups of Bisulphited Wools.** S. Blackburn, R. Consden and H. Phillips. *Biochem. J.*, 1944, 38, 25-29. The thiol groups produced when wool is treated with sodium bisulphite can be methylated by methyl iodide or methyl bromide; the S-cysteinesulphonate groups are unaffected. A similar reaction occurs when wool is treated simultaneously with sodium bisulphite and dimethyl sulphate. A technique for the isolation of S-methylcysteine from hydrolysates of S-methylated wools by partition chromatography of the N-acetylated amino-acids is described. W.

**The Chemistry of Protein Denaturation.** H. Neurath, J. P. Greenstein, F. W. Putnam and J. O. Erickson. *Chem. Reviews*, 1944, 34, 157-265. An extremely comprehensive review covering all aspects of the subject. 418 references are included. W.

**Insect Cage Olfactometer.** G. A. Hepburn. *Onderstepoort J.*, 1943, 18, 7-12. A simple type of cage olfactometer is described. This has been evolved for studies of sheep blowflies, particularly *Lucilia cuprina* Wied., but with modifications may be used for studying the olfactory responses of various species of insects. W.

**Prevention and Treatment of Blowfly Strike in Sheep: Recent Advances.** *Australia: Council Sci. Ind. Res., Bull.* 174, 1943. Supplement to Report No. 2 of Joint Blowfly Committee (these *Abs.*, 1940, A593). Attention is drawn to

improved methods for preventing and treating blowfly strike evolved since the publication of Report No. 2. Work on selection and breeding indicates that the use of plain parents is not sufficient to obtain a high percentage of A class (plain-breeched) sheep, and that the use of progeny-tested rams is necessary. In breeding towards plainness of the breech, there has been no loss in the quality and weight of wool produced. Short docking of the tail should be avoided; the tip of the healed stump should reach just below the tip of the vulva. A modified form of the Mules operation is described; this aims not only at removing the folds of skin from the centre of the breech, but also at producing the maximum expansion, by stretching, of the "bare area." Details are given of two improved boric acid dressings, B.T.B. and B.K.B. W.

**Upland Cotton: Inheritance of Green and Brown Lint.** T. R. Richmond. *J. Amer. Soc. Agron.*, 1943, 35, 967-975 (through *Plant Breed. Abstr.*, 1944, 14, 142). The genetical behaviour of lint pigmentation in cotton has been studied on Texas Green Lint, Nankeen (dark brown lint), Texas Rust (light brown lint), Higginbotham (light brown lint) and normal white-linted varieties. Pigmentation of the first three varieties is conditioned by a single gene which is incompletely dominant to white. The genes for Texas Rust and Nankeen are allelic and appear to be independent of Texas Green Lint and Higginbotham which are also independent of each other. An association was observed between the green and brown lint genes and a reduction in the weight of fibre per unit length. C.

**Aspergillus Glaucus: Effect of Atmospheric Humidity.** B. Stille. *Vorr. Pfl. Lebensm.-Forsch.*, 1942, 5, 403-408 (through *Chem. Zentr.*, 1943, ii, 967 and *Rev. Appl. Mycol.*, 1944, 23, 161). *Aspergillus glaucus* is extremely xerophile, being the last of the organisms tested to cease growth with declining atmospheric humidity; the germination and spore formation limits were 70 and 74 per cent. R.H., respectively, at the optimum temperature of 31° C. In practical storage trials with unpacked dried vegetables at 31°, 77 per cent. R.H. was the lower limit for risk of spoilage by *A. glaucus*. No other dried products are as sensitive to fungal damage as vegetables. C.

**Coloured Solutions: Acidity Determination.** V. B. Evstigneev. *Zavod. Lab.*, 1940, 9, 1032-1034 (through *Brit. Chem. Physiol. Abstr.*, 1944, C, 1). The acid solution in the cell quinhydrone electrode, acid solution|saturated potassium chloride|mercurous chloride, mercury is titrated until the e.m.f. of the cell vanishes. C.

**Potato Starch Moisture: Determination.** W. L. Porter and C. O. Willits. *J. Assoc. Offic. Agric. Chemists*, 1944, 27, 179-194. Methods for the determination of moisture in cereals and similar products are reviewed, and an account is given of investigations of determinations of the moisture content of starch by distillation procedures, the Karl Fischer chemical method, and gravity convection, mechanical convection, and vacuum oven methods. The effects of time and temperature on the loss in weight of potato starch on oven drying were determined. It was found possible to obtain reproducible results by heating to constant weight at temperatures in the range of 135-145° C. in the Brabender moisture tester and the adoption of this procedure as a basic method is proposed. Modifications of some of the other methods are described that lead to results in agreement with those of the basic method. C.

**2:4-Dinitroaniline: Determination in Food and Drug Dyes.** O. L. Evenson. *J. Assoc. Offic. Agric. Chemists*, 1944, 27, 131-134. Details are given of a colorimetric method for the determination of 2:4-dinitroaniline in D & C Orange No. 17, in which the intermediate is extracted with ether and determined by the intensity of its red colour with aqueous-alcoholic sodium hydroxide. The spectral characteristics of this colour are shown by extinction curves. C.

**Food Dye D & C Red No. 18: Analysis, Purification and Spectrum.** S. H. Newburger. *J. Assoc. Offic. Agric. Chemists*, 1944, 27, 134-139. A method for the determination of D & C Red No. 18 involves conversion of the dye to a water-soluble product by sulphonation, and titration with a standard solution of titanium trichloride. A procedure for the purification of the commercial dye is described. Extinction curves of the dye at various stages of purification and in chloroform solution at various concentrations, in the spectral region 400-750

$m\mu$ , are presented together with the extinction curve of the sulphonated dye. Spectrometric determinations are possible. C.

**Glucose: Photometric Determination.** N. Nelson. *J. Biol. Chem.*, 1944, **153**, 375-380. A photometric method is described for the determination of glucose (or reduction equivalent) with copper reagents and an arsenomolybdate reagent, details of the preparation of which are given. Representative data show that the optical density of the colour developed is proportional to the glucose taken and is stable over long periods of time. Applications of the method to the determination of glucose in blood filtrates are discussed. C.

**Wax: Determination in Paper Sizing Products.** W. E. Shaefer and A. C. Dreshfield. *Paper Trade J.*, 1944, **118**, *TAPPI*, 210. The authors' method depending on the solubility of wax in hot acetic anhydride and relatively low solubility in the cold has been modified to make it more suitable for pastes and certain dry sizes. One litre of a mixture of acetic anhydride (95) and acetic acid (5) is heated with 10 grams of wax of the type under test, cooled to about 25° C. and decanted through a fine copper screen. One portion is then cooled to 0-2° C. and another to 20° C., and filtered rapidly, to give the extracting solvent and the washing liquid, respectively. C.

**Cellulose: Nitration in Nitric Acid Vapour.** G. I. Wilson and F. D. Miles. *Trans. Faraday Soc.*, 1944, **40**, 150-163. A weighed bundle of ramie was suspended on a quartz-spring balance and a stream of nitric acid vapour was passed through it at the desired pressure. Experiments were carried out at pressures of 4-16 mm., temperatures of 20° and 40° C., and various times up to 40 hours, and at the end of each run the product was analysed and the degree of nitration found. From this and the final weight indicated by the quartz spring, the nitric acid absorbed and that which had reacted were calculated. The water present as a result of nitration was estimated. Measurements were also made at several temperatures and pressures of the absorption of nitric acid molecules on fully nitrated cellulose. The results show that absorption of nitric acid on the cellulose fibres takes place and reaches a maximum in about three hours. The nitration reaction is a consequence of this absorption and attains its greatest rate about the same time that the absorption reaches its maximum. This rate of nitration is independent of the pressure of nitric acid vapour in the gas-phase, but is related to the amount of acid which is absorbed without chemical reaction. The rate of nitration is roughly proportional to the square of this absorbed amount. From this it is inferred that two molecules of nitric acid are concerned in the conversion of a hydroxyl group—one to nitrate it, the other to accept the water of reaction. The chemical equation is therefore  $-\text{OH} + 2\text{HNO}_3 = -\text{O}\cdot\text{NO}_2 + \text{HNO}_3\cdot\text{H}_2\text{O}$ . This view of the reaction is supported by the fact that for denitration both water and nitric acid must be present, water alone being ineffective. Certain necessary modifications of the simple equation, rate of nitration =  $K$  (absorbed nitric acid)<sup>2</sup>, are discussed. The presence of water of reaction undoubtedly reduces the number of active  $\text{HNO}_3$  molecules. Absorption on nitrate groups must take place, but the influence of this is uncertain. An equation which is preferred and fits the experimental data contains two correction terms for these effects. The evaluation of these terms is described and the calculated and experimental values of the reaction rate are compared. Cellulose nitrate prepared in this way contained up to 13.4 per cent. N. Fractionation showed the products to be of abnormal solubility in acetone. C.

**Nitrocellulose: Denitration.** K. Fabel. *Nitrocellulose*, 1941, **12**, 143-146 (through *Chem. Zentr.*, 1941, **ii**, 3127 and *Chem. Abstr.*, 1944, **38**, 2199<sup>b</sup>). On centrifuging nitrocellulose wet with acid, partial denitration occurs, resulting not only in lowered yields of nitrocellulose, but also in reduced clarity of solutions and films prepared from the nitrocellulose. This denitration is avoided by preventing access of air during centrifuging. X-Ray investigation of the denitration process is discussed. C.

**Nitrocellulose: Solubility in Mixtures of Ether and Alcohol.** A. Kraus. *Nitrocellulose*, 1941, **12**, 123-124 (through *Chem. Zentr.*, 1941, **ii**, 3127 and *Chem. Abstr.*, 1944, **38**, 2199<sup>g</sup>). The solubility of nitrocellulose in mixtures of ether and alcohol is explicable on the basis of the similarity of the polar char-

acter of the latter to that of the nitrocellulose molecule. With increasing nitrogen content of the nitrocellulose, increase in the proportion of ether in the mixture is more favourable. C.

**Polysaccharides: Oxidative Degradation.** G. Jayme, M. Sätre and S. Maris. *Naturwissenschaften*, 1941, 29, 768-769 (through *Chem. Abstr.*, 1944, 38, 2197<sup>b</sup>). Low yields of glyoxal and erythronic acid were obtained when cellulose or starch was oxidised with 10 per cent. periodic acid at pH 1. Oxidation of cellulose with buffered 10 per cent. periodic acid at pH 3.5-4.0 transformed C<sub>2</sub> and C<sub>3</sub> into aldehyde groups in 97.5-99 per cent. yield, the polymeric otherwise remaining unchanged. The new compound was insoluble in the oxidising solution, but 95 per cent. was soluble in boiling water. After hydrolysis with 0.1N. sulphuric acid, glyoxal in 39.3 per cent. yield could be isolated as the phenylosazone. Xylan, oxidised and treated in like manner, yielded 62.4 per cent. of glyoxal. Glyceraldehyde, formed during the oxidation from C<sub>3</sub>, C<sub>4</sub> and C<sub>5</sub> of the carbohydrate, was isolated in 44.9 per cent. yield as the methylglyoxalosazone by distillation from 20 per cent. sulphuric acid. Further oxidation of the original periodic acid oxidation product gave rise to glyceric acid which was isolated after sulphuric acid hydrolysis in 65.2 per cent. yield as the brucine salt. When the original periodic acid oxidation product was reduced with hydrogen and a Raney-nickel catalyst, glycerol and glycolaldehyde were isolated after hydrolysis. Better yields of the latter two compounds were obtained by frequently alternating reduction and hydrolysis. In this manner a mixture of glycerol and glycol was obtained in 51.6 per cent. yield, 76.5 per cent. of which was glycerol. Oxidation of powdered straw with buffered periodic acid yielded 20 per cent. of a soluble oxidation product. The insoluble material upon further bromine oxidation gave rise to a mixture of organic acids. C.

**Starch: Acetylation.** L. T. Smith and R. H. Treadway. *Chem. Eng. News*, 1944, 22, 813-817. A report is given of investigations into the best conditions for acetylating starch by (1) mixtures of acetic acid, acetic anhydride and a catalyst, and (2) acetic anhydride alone after a swelling treatment. The second method, under the best conditions, led to complete acetylation, with but slight degradation, in 1 hour as against 9 hours for the first method. The products were comparable with cellulose acetate in viscosity. The best swelling treatment was the application of 90 per cent. formic acid to oven-dry starch. C.

**Potato Starch: Composition.** M. Samec, V. Pirkmajer, J. Počkar, T. Serneck and L. Žagar. *Österr. Chem.-Ztg.*, 1941, 44, 154-160 (through *Chem. Zentr.*, 1941, ii, 2687 and *Chem. Abstr.*, 1944, 38, 2232<sup>b</sup>). Viscosity measurements of the erythroamylose, electrical conductivity of amylopectin solutions, splitting of phosphoric acid from the latter, and studies of the nitrogen-containing compounds of starch grains, together with previous work, show that potato starch is a compound of amylose and erythroamylose. The latter is bound to phosphoric acid in the gel phase. This fraction separates after splitting the glucose chain which only the erythroamylose possesses. C.

**Wheat Starch: Production.** R. L. Slotter and C. T. Langford. *Ind. Eng. Chem.*, 1944, 36, 404-408. An account is given of the development of a process for extracting starch and other products from whole wheat kernel, which is analogous to the process used in the wet milling of corn. Operating data are given for typical runs in a pilot plant. Yields as high as 80 per cent. of the starch contained in the grain can be obtained. The starch obtained is of better colour, contains less protein, and gives more viscous pastes than the average commercial wheat starch at present available. It is an excellent raw material for the production of syrups and sugars. Good starch can be extracted from wheat that is unsuitable for food. C.

**Sericin: Denaturation.** Z. Hirose. *J. Agr. Chem. Soc. Japan, Bull.*, 1940, 16, 176-179 (through *Chem. Zentr.*, 1941, i, 3313 and *Chem. Abstr.*, 1944, 38, 2214<sup>g</sup>). The preparation and isolation of  $\alpha_{3,8}$ -sericin,  $\alpha_{4,4}$ -sericin and  $\alpha_1$ -sericin are described. The  $\alpha_{4,4}$ - and  $\alpha_1$ -sericins absorb more acid dyes and tannin, combine with more iodine and contain more aromatic acids and tryptophan than  $\alpha_{3,8}$ -sericin, whilst the latter absorbs more basic dyes. The isoelectric point for  $\alpha_{4,4}$ -sericin lies at 3.7-3.8, that of  $\alpha_1$ -sericin near 4.2. When  $\alpha$ -sericin is treated with hot water, an insoluble portion,  $\alpha_1$ -sericin, is formed, and the

isoelectric point is shifted more to the alkaline side than for the initial material.

C.

**Sericin: Properties.** D. Cagnoni. *Seta*, 1941, 47, 230-231 (through *Chem. Zentr.*, 1941, ii, 2511 and *Chem. Abstr.*, 1944, 38, 2214<sup>2</sup>). Cocoons dried at 70-80° were extracted in metal vessels at 118°. The solution was evaporated to dryness in a desiccator under a current of air. The sericin was obtained in the form of brittle flakes, which were white or yellowish, depending upon the strain used. For more accurate examination a 1 per cent. solution was prepared at 110° and the time required for gelling this solution at 6° was determined. The viscosity of the gelled solution was also determined. Tables are given in the original paper.

**Zein Solvents: Critical Peptization Temperatures.** C. D. Evans and R. H. Manley. *Ind. Eng. Chem.*, 1944, 36, 408-410. Solvents for zein are classified broadly into (a) primary solvents, such as various acids, amines, amides and hydroxides, which are capable in themselves of dispersing zein, (b) secondary solvents, such as chloroform, nitromethane, formaldehyde, acetoacetic ester, benzene and toluene, which are not themselves solvents, but may assist primary solvents in mixtures, and (c) indifferent diluents, e.g. hexane, ether and ethyl acetate. Ternary mixtures are discussed and trilinear diagrams for critical peptization temperatures are presented. Ternary solvent systems for zein composed of acetone, water and formaldehyde are similar in solvent characteristics to ethyl alcohol-water-formaldehyde mixtures, but are distinctly superior in their resistance to gelation. The addition of rosin or shellac to binary solvents, such as alcohol and water, substantially lowers the critical peptization temperatures of zein in these mixtures. The presence of rosin in such systems greatly reduces the tendency of the protein dispersion to set to an irreversible gel. C.

**$\alpha$ -Amino Acids: Ammonia Evolved by Ninhydrin; Determination.** D. A. MacFadyen. *J. Biol. Chem.*, 1944, 153, 507-513. Details are given of a method for the determination of the ammonia evolved from primary  $\alpha$ -amino groups of amino acids on reaction with ninhydrin. The procedure comprises (1) reaction with ninhydrin in boiling aqueous solution at pH 2.5, (2) removal of the ninhydrin as an insoluble derivative, hydrindantin, (3) transfer of the ammonia to an acid solution by the aeration procedure of Van Slyke and Cullen, and (4) determination of the ammonia in the acid solution by titration or by manometric measurement by the hypobromite method. Results of determinations of amino groups in various compounds by nitrous acid, ninhydrin-carbon dioxide and ninhydrin-ammonia methods are presented. Glycine and alanine yield only 0.86 and 0.90 mole of ammonia by the ninhydrin method, and tryptophane undergoes an anomalous reaction, yielding only 0.34 mole of ammonia. Under the described conditions,  $\beta$ -alanine and  $\alpha$ -glucoseamine are inert to ninhydrin, and urea does not yield ammonia. C.

**$\beta$ -Eleostearic Acid: Autoxidation.** R. W. Brauer and L. T. Steadman. *J. Amer. Chem. Soc.*, 1944, 66, 563-569. An account is given of a method for the study of the autoxidation of fatty acids in liquid solutions by oxygen uptake measurements and by the simultaneous determination of the absorption spectra of the autoxidising solutions. Curves showing the relation between the rate of oxygen uptake of  $\beta$ -eleostearic acid and the initial concentration of the substrate are presented. The spectrographic changes suggest that during the reaction a conjugated diene is formed which in turn undergoes autoxidation. A method of computing the rate of triene destruction from the oxygen uptake curves and the relation between absorbed oxygen and residual intact triene groups is explained. In order to destroy 1 mol. of  $\beta$ -eleostearic acid, slightly less than 0.5 mol. of oxygen is required initially. Consequently, it is assumed that (a) the initial uptake of oxygen by  $\beta$ -eleostearic acid results in a dimerization involving the formation of some C-C bonds and (b) a parasitic polymerization reaction is induced by the peroxides formed in the course of the reaction. The formation of dimeric products in the reaction has been verified by molecular weight determinations. The amount of oxygen taken up can be computed approximately for the early stages of the reaction from the extinction coefficients of the diene and triene bands if the following sequence of reactions is assumed:  $2(-C:C-)_3 + O_2 \rightarrow (-C:C-)_2$  and  $(-C:C-)_2 + O_2 \rightarrow$  (spectrographically inert products capable of taking up 2 mols of oxygen per mol of original  $\beta$ -eleostearic acid). The rate of oxygen absorption by  $\beta$ -eleostearic acid

becomes insignificant after an uptake of 2 mols of oxygen per mol of  $\beta$ -eleostearic acid. This amount of oxygen can be recovered in a dibasic acid which is probably a dimeride of the original acid. Three-fourths of the absorbed oxygen in this product is removed by treatment with alkali. C.

**Stearic and Abietic Acids: Separation.** G. Papps and D. F. Othmer. *Ind. Eng. Chem.*, 1944, 36, 430-434. A method for the separation of the two main components of hydrogenated tall oil, stearic and abietic acids, is described which depends on selective adsorption on activated carbon. An 8 per cent. solution of the hydrogenated oil in a suitable solvent is passed through a glass column containing activated carbon, and after the oil is fixed on the adsorbent, the abietic acid is first washed out by the use of additional fresh solvent, followed by the stearic acid which is preferentially adsorbed. Of 29 solvents studied, 1-nitropropane was found to be the most suitable. For the evaluation of the solvents, adsorption isotherms were determined for pure stearic and abietic acids adsorbed on activated carbon at 35.5° C., and for 50 per cent. mixtures of the two acids. It was found that the types of adsorption isotherms given by pure stearic acid and pure abietic acid in the same solvent are usually similar. For a family of compounds, e.g. aromatic hydrocarbons, nitroparaffins, or aliphatic alcohols, as the molecular weight of the solvents increases, there is a shift of the isotherm with less adsorption and decreasing differences. The individual adsorption isotherms of a compound do not necessarily predict the course of adsorption of a mixture containing the compound, when the same solvent is used. Stearic acid, which is adsorbed to a greater extent in the individual isotherms, is adsorbed to an even greater extent from the solutions of both stearic and abietic acid. The stearic-abietic system, in different solvents, reverses the general rule in adsorption, that unsaturated compounds are preferably adsorbed to saturated ones. Details are given of a modified McNicoll method for the determination of abietic acid in mixtures, based on selective esterification of fatty acids in the presence of  $\beta$ -naphthalenesulphonic acid. C.

**Berndel Filter: Characteristics and Uses.** E. Manegold and C. Böhme. *Kolloid Z.*, 1943, 103, 96-104 (through *Brit. Chem. Physiol. Abstr.*, 1944, C, 53). The Berndel filter, consisting of a bundle of 7<sup>n</sup> or 19<sup>n</sup> glass capillary tubes is described and photo-micrographs are given. The 19<sup>2</sup> and 19<sup>5</sup> filters have been examined from the physico-colloidal viewpoint. The specific gravity, pore volume, the specific transmission for water and for dry and damp gases, the capillary pressure for an air/water surface, and the capillary width distribution curve have been determined. Technical uses of the filter are discussed. The filtration of a dilute suspension of red blood corpuscles with a disc diameter of 0.8  $\mu$ , with a 19<sup>4</sup> filter having a mean pore width of 5.5  $\mu$ , has been investigated. The filter contains spaces which exceed the capillary width in diameter, so that the filter itself cannot be adequately tested. The possible uses of the apparatus in bacteriology, and for the production of foams and emulsions, and as a spinneret for threads are mentioned. C.

**Polyamide Ultracentrifuge Tubes and Cells: Stability.** G. Bergold. *Kolloid Z.*, 1943, 102, 292-293 (through *Brit. Chem. Physiol. Abstr.*, 1944, C, 52). Centrifuge tubes made from three different polyamides (Igamides) are not shattered by fields of 150,000 g. Type A is translucent, sterilisable by heat, stable to most solvents, and only sensitive to phenol, acid amides, concentrated sulphuric acid, and 80 per cent. formic acid. Type B is transparent, sterilisable by heat, and sensitive to organic solvents, but stable to caustic soda and hydrochloric acid up to 2N. Type C is glass clear, not completely stable to heat, and sensitive to organic reagents, but stable to mercuric chloride, caustic soda, and hydrochloric acid up to 2N. The materials can also be used for construction and packing in other parts of the ultra-centrifuge. C.

**Starch Grains: Structure and Swelling Mechanism.** E. Höppler. *Kolloid Z.*, 1942, 101, 305-312 (through *Chem. Abstr.*, 1944, 38, 2232<sup>7</sup>). In the esterification of native potato starch with halogenated fatty acids, sodium glycollates of starch are obtained. The individual components, Na amylocellulose glycollate, Na amylopectin glycollate and Na amylose glycollate are identified by their different solubilities in aqueous methyl alcohol, and can be obtained in pure form. Sodium amylopectin glycollate has valuable colloidal properties and is displacing tragacanth in technical work. The 1 per cent. solution is clear and stable and its viscosity is 1,000 times that of water. Four different types of

structure can be observed in potato-starch grains: (1) pervading fine stratifications without an amylocellulose outer membrane; (2) relatively thick outer membrane and without an inner stratified structure; (3) double outer membranes; and (4) without outer membranes and without stratification, but with radial spherocrystalline structure. The particular structure is reflected in the swelling mechanism of the starch. Exhaustive observations on starch grains from *Dieffenbachia seguine* indicate the apposition growth of the starch grain. C.

**Amyloses: Viscosity and Molecular Weight.** J. F. Foster and R. M. Hixon. *J. Amer. Chem. Soc.*, 1944, 66, 557-560. Results are given of osmotic pressure measurements on solutions of corn and tapioca amylose acetates in chloroform; they lead to molecular weights of 42,000 and 75,000, respectively, corresponding to 260 and 460 glucose units. Results of measurements of the viscosities of solutions of corn, tapioca and potato amylose acetates in chloroform are shown graphically. These results and data for other members of the series indicate a dependence of the intrinsic viscosity on a power of the molecular weight greater than unity, confirming expectations from the comparative rigidity of Fischer-Hirschfelder models of amylose. The rigidity of acetylated amylose molecules in chloroform appears to be the same as that of amylose in ethylenediamine. C.

**Potato and Sweet-potato Starches: Viscosity and Microscopical Properties.** H. N. Barham, J. A. Wagoner, B. M. Williams and G. N. Reed. *J. Agric. Res.*, 1944, 68, 331-345. Varietal and environmental differences in potatoes and sweet-potatoes are reflected in viscosity, gelatinisation temperature, granule size, and granule size frequency measurements of the starches obtained from them. There is no direct correlation of the granule size and granule size frequencies, as affected by such differences, with either the viscosity or the gelatinisation temperature, nor are the gelatinisation temperature and viscosity directly related. It may be assumed that varietal and environmental factors in some manner affect the structure of the starch granule. The gelatinisation temperature, based on the loss of anisotropy, does not necessarily correspond to that part of the viscosity curve between zero viscosity and the initial maximum. Five hundred granules seem to be a sufficient number to count in order to obtain the average size and the size frequency. A smaller number than this does not always permit a reliable statistical treatment. Curing of the sweet-potatoes lowers the gelatinisation temperature, the granule size, and the viscosity of the starches, indicating a change in the nature of the granule during the curing. The late harvest of potatoes tends to raise the gelatinisation temperature and to decrease the viscosity, but the average size of the granules is either smaller or larger, depending upon the variety. The Warba variety of potatoes and the Little Stem Jersey variety of sweet-potatoes formed the most viscous pastes and the ones that thinned out least during cooking. Starches obtained from Kansas potatoes and sweet-potatoes are of good quality and are the equal of commercial starches if, in the case of potato starch, the basis for comparison is extracted starch. C.

**Potato Starch Grains: Optical Properties.** H. Speich. *Ber. schweiz. botan. Ges.*, 1942, 52, 175-214 (through *Chem. Abstr.*, 1944, 38, 2233<sup>3</sup>). The degree of swelling of potato starch grains that had been carefully dried over phosphorus pentoxide was determined when dispersed in 28 different liquids. Volume changes varied from 68.88 per cent. increase in glycol to 7.2 per cent. decrease in salicylaldehyde. For water the increase was 57.99 per cent. In general the more hydrophilic the liquid, the greater the swelling and the more lipophilic, the less the swelling of the starch grains. According to birefringence determinations, potato starch grains behave toward water, water-alcohol mixtures, alcohols and aldehydes as permeable aggregates of small rods, whilst toward lipophilic (non-polar) liquids, they appear to possess homogeneous sub-microscopic structures. Differences of birefringence can be demonstrated in different parts of the grains (0.0134 whole grain; 0.0124 periphery). For a wave length of 589 m $\mu$  and temperature of 25° the refractive index is 1.535 in the direction of the optical axis and 1.535 at right angles to it. Relative to temperature effects on refraction, the behaviour of the starch grains is between that of solid and liquid bodies. X-Ray diagrams of the carefully dried starch grains show no well defined crystal lattice structure, but a less well organised molecular frame-work. One of the 13 tables that are included compares the optical properties of potato starch grains with those of cellulose from ramie fibres. C.

**Flow Meters: Design.** H. Ziebolz. *Rev. Sci. Instruments*, 1944, 15, 80-87. The variables entering into the flow measurement problem are analysed and basic solutions are studied in relation to the design of flow meters. Various types of instruments are critically discussed. C.

**Geon Resins: Characteristics.** B.F. Goodrich Co. *Rev. Sci. Instruments*, 1944, 15, 136. Geon resins are thermoplastic and of two chemical types. Geon 100 series are special polymers of vinyl chloride characterised by thermal and light stability, toughness and chemical inertness. Geon 101 is designed for electrical applications and Geon 102 for general service. The vinyl chloride: vinylidene chloride copolymers of the Geon 200 series combine increased solubility and thermoplasticity with exceptional stability, chemical resistance and wide useful temperature range. They are unusually stable to light and to thermal decomposition and, in the field of vinyl chloride copolymers, their resistance to hydrolysis by boiling water and hot alkalis is outstanding. Geon resins can be modified by formulation to compositions varying in properties from a rigid thermoplastic, through an elastomeric range, to a very soft jelly. Outstanding in the elastomeric range are the combinations of rubberlike properties with non-flammability and resistance to oxidation. In comparison with other vinyl thermoplastics, compositions of the 100 series Geons are characterised by their resistance to deformation at elevated temperatures. Applications of Geon resins and plastics include insulation and protective jackets for wire and cable, extruded tubing, gaskets and packing, moulded products, protective coatings, and coated fabrics and papers. C.

**Plastacele: Properties.** E. I. Du Pont de Nemours & Co. Inc. *Rev. Sci. Instruments*, 1944, 15, 136. Plastacele, a cellulose acetate plastic for transparent enclosures, windows, shields and partitions, is produced in colourless sheets from 0.020 in. to 0.250 in. and in maximum dimensions of 21 × 51 ins. It is also made in transparent, translucent, and opaque colours. Its surface hardness is comparable to that of aluminium and copper and it can be scratched by materials which will scratch these metals. It can be fabricated by procedures which are in many respects similar to those used for wood, soft metals and other plastics, such as Lucite methyl methacrylate resin. Machinability is improved by conditioning for at least 24 hours at 80-90° F. and about 55 per cent. R.H. A strong blast of air directed at the point of contact of the tool and the plastic will usually suffice to dissipate the heat generated during machining and will at the same time remove chips and shavings from the work. Plastacele can be bent or formed into simple or complex shapes by preheating to a temperature between 250° and 275° F. A table is given showing the general physical properties of Plastacele C-7517-Transparent-Aircraft Grade. C.

**Silkworm: Urea Content.** G. D. Bottero. *Arch. ist. biochim. ital.*, 1940, 12, 199-208 (through *Chem. Zentr.*, 1941, ii, 2965 and *Chem. Abstr.*, 1944, 38, 2397<sup>2</sup>). During larval development of the silkworm (*Bombyx mori*) there is a continuous rise in urea content, reaching a maximum at the time of the resting stage and decreasing to a very low level after moulting. A similar decrease in the urea content was observed also after the greatest growth rate had been achieved at the time of maturity. Each time the silkworm enters a stage of morphogenetic activity it frees itself from the urea accumulated during the development period either by excretion or by enzymic decomposition. The blood of such organisms reveals *in vitro* urease activity. C.

**Iron: Determination with o-Phenanthroline.** S. L. Bandemer and P. J. Schaible. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 317-319. For the determination of iron in organic materials by the o-phenanthroline method the ashed materials are dissolved in dilute hydrochloric acid, sodium acetate is added to aliquot parts to adjust the pH to 3.5, followed by hydroquinone to reduce the iron, and o-phenanthroline to develop an orange-pink colour which is evaluated by means of a photometer using a Corning No. 430 blue-green filter. A critical study of this method has shown that sodium citrate is more satisfactory than the acetate for adjusting the pH. If the pH is adjusted before the introduction of o-phenanthroline, the rate of colour development is influenced by such factors as the time interval between the addition of reagents, temperature of the solutions, type and amount of phosphate present, amount of citrate, and length of time the solutions stand before the photometer reading. If the sodium citrate is added after the hydroquinone and o-phenanthroline at tem-

peratures above 20° C., these factors do not adversely affect the recovery of iron. Under these conditions, maximum colour is developed when the solutions stand only 30 min. For samples of similar materials of approximately the same size, it is expedient to use an average volume of citrate rather than to titrate each sample individually. A modified procedure for the *o*-phenanthroline determination of iron, incorporating improvements suggested by the results of this study, is described. C.

**Tin: Colorimetric Determination.** I. Baker, M. Miller and R. S. Gibbs. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 269-271. A rapid and accurate method for the determination of tin in concentrations ranging from 0.0005 to 0.5 per cent. depends on the development of a blue colour when chlorostannous acid reacts with a silicomolybdate reagent. The tin is separated from an acid solution of the sample by distillation and the distillate used for the colorimetric determination. Micro- and macro-procedures are described. The effects of various ions are discussed, and results of determinations on samples of steel and bronze containing known quantities of tin are presented. C.

**Coloured Materials: Potentiometric Acidity Determination.** L. Lykken, P. Porter, H. D. Ruliffson and F. D. Tuemmler. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 219-234. Potentiometric methods for the determination of free and combined acidity of materials soluble only in non-aqueous solvents are presented; they are particularly applicable to highly coloured or opaque materials such as used lubricants or lubricants containing various additives, and asphalt, emulsions, resins, etc. The free acidity, or basicity, is determined by titrating the sample in a benzene-isopropyl alcohol solution, using a glass-calomel electrode system. The combined acidity is similarly determined by potentiometric titration with alcoholic acid after saponifying the sample dissolved in benzene and isopropyl alcohol containing an excess of strong base. Inflection points and fixed cell potentials are used for the estimation of end points. The determination by a single titration of two or more components of a mixture of acids or bases not distinguishable in an aqueous titration, and phenomena which make possible the estimation of ionisation constants of acids and bases having limited solubility in water, are briefly described. C.

**Leuco Crystal Violet: Spectrophotometric Determination.** W. Seaman, A. R. Norton, J. T. Woods and J. J. Hugonet. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 336-339. Details are given of a method of determining leuco crystal violet by oxidising with benzoyl peroxide and measuring, with a spectrophotometer, the intensity of the colour produced. The standard deviation for a single value is  $\pm 0.25$  per cent. of the total leuco crystal violet. The effect of impurities upon the accuracy is discussed. C.

**Oils: Fluorocolorimetric Determination.** H. Benjamin. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 331. For the determination of the concentration of sulphurized cutting oils blended with straight mineral oil ultra-violet rays were supplied by a bank of four 2-watt argon bulbs, the visible rays being filtered by a Wratten ultra-violet ray filter. Strips of blotting paper were impregnated with standard samples of the oils made up to definite concentrations and these, because of the fluorescent nature of the oil itself, produced a sharp gradation of colours. Samples were then matched to the standards. As the concentrations of the various blends could be related graphically to the viscosity, it was only necessary, when desired, to refer to an appropriate curve to express the fluorescent-colorimetric determination in terms of Saybolt seconds. To determine concentrations of oil in oil-water emulsions, samples of known oil concentrations were prepared and the unknown sample compared with them. In order to remove interfering materials the tests were carried out with ether extracts of the emulsion samples and standards. Oils and waxes which do not fluoresce can be determined in a similar manner by adding suitable oil-soluble fluorescent dyes. Ultra-violet light can be used to detect traces of oil on metal parts after cleaning. C.

**Cotton Cellulose: Deposition.** W. Wergin. *Planta*, 1942, 32, 535-546 (through *Chem. Zentr.*, 1942, ii, 2042 and *Chem. Abstr.*, 1944, 38, 2361<sup>7</sup>). The colourless particles that appear in the cytoplasm of cotton hairs are not cellulose structures from which the fibrils are formed by linear extension as stated by Farr, but plastids in which by special treatment starch can be demonstrated. Microscopy also shows that these plastids are not in contact with the fibrils as

if the better to be incorporated into the cell walls; it is more likely that the formation of cellulose takes place at the walls. C.

**Sodium Stearate and Palmitate Crystals: Production.** A. de Bretteville, Jr. *J. Phys. Chem.*, 1944, 48, 154-158. Sodium stearate can be crystallised only at a critical concentration below the gel point in an alcohol solution. Sodium palmitate cannot be crystallised below the gel point, but does give crystals on the addition of a pinch of sodium chloride, which appears to act as a nucleus for crystal growth. The preparation and habit of single crystals of Na stearate and palmitate are described. Photographs are reproduced. C.

**Sulphite Waste Liquor: Ultrachromatographic Adsorption.** G. A. Schröter. *Papier-Fabr. Wochbl. Papierfabr.*, 1943, No. 2, 50-54 (through *Chem. Abstr.*, 1944, 38, 2486<sup>9</sup>). Pure glucose and xylose were slightly adsorbed by Floridin XXF from aqueous solution, but only the former was sorbed to a slight extent from a spruce waste sulphite liquor diluted 1:10, the reducing value dropping from 0.23 to 0.21 per cent. Filtrates from Floridin XXF showed a pale blue fluorescence in ultra-violet light. When filtered through Frankonit K1, the diluted sulphite liquor yielded a sulphur fraction that showed a very weak blue fluorescence and which, although giving a positive tryptaflavin reaction, gave no test with  $\beta$ -naphthylamine-hydrochloric acid; this indicated the possible presence of a non-fluorescent  $\beta$ -lignosulphonic acid. After passage of the sulphite liquor and rinsing with water, a substance with violet fluorescence was obtained from Frankonit K1. The fraction that contained sulphur was converted into a barium salt containing about C 38.4, H 4.1, S 7.8, MeO 9.1 and Ba 21.5 per cent. which, however, was not homogeneous. When a beechwood sulphite waste liquor was passed through aluminium oxide (buffered to pH 5), several ultra-violet fluorescent zones were noted, one of which was intensely yellow. By extraction from the aluminium oxide with 2 per cent. ammonium hydroxide, the substance responsible for this yellow fluorescence was isolated as a compound high in ash, containing nitrogen and about 1.6 per cent. sulphur. However, this appears to be a secondary product of beechwood sulphite waste liquor since a sulphite waste liquor made from beechwood in the laboratory at first showed a pure violet fluorescence, but on heating to 135° for 2 hours, also gave yellow fluorescing zones when passed through aluminium oxide. When the spruce waste sulphite liquor was passed through aluminium oxide several strongly fluorescing zones formed. One of these (very strongly sorbed) initially showed an intense white-blue-violet fluorescence which disappeared on contact with sulphur dioxide, but returned on rinsing with water. Similar reactions and sorption were noted with a calcium lignosulphonate that had been precipitated by alcohol from spruce waste sulphite liquor. However, these reactions are not proof that the original fluorescing material was actually a lignosulphonate. Aluminium oxide adsorbs very little reducing sugar from spruce waste sulphite liquor. C.

**Wood: Reaction with Diazo Compounds.** F. Schütz and P. Sarten. *Cellulose-chemie*, 1943, 21, 35-48 (through *Chem. Abstr.*, 1944, 38, 2483<sup>7</sup>). Wood is not coloured by diazo compounds, but alkali-treated wood, alkali lignin, phenol lignin and lignosulphonic acid give a red coloration and glucose and other aliphatic and aromatic aldehydes give intensive red colours. An investigation of the reaction between wood and diazo compounds shows that no normal coupling products are formed as with phenols, amines, etc., but oxidation takes place. Details are given of investigations of the products formed by reaction of diazo compounds with wood, glucose and acetic acid lignin, and of the effects of heating air-dried wood at 120.5°, and extracting wood with hot water, alcohol, acetone, etc. The results support the view that lignin is not an original wood component, but a reaction product of the wood lower in water and therefore higher in carbon content. The economic prospects of an extraction of wood with water before pulping and the utilisation of the extracts are discussed. C.

**Wetting Liquids: Contact Angles and Adsorption.** H. K. Livingston. *J. Phys. Chem.*, 1944, 48, 120-124. Available experimental data for solid-liquid-vapour systems are quoted and it is pointed out that for most two-component solid-liquid-vapour systems the contact angle is zero ( $\theta=0$ ) and the solid surface is completely covered with adsorbed molecules from the vapour at saturation pressure ( $\sigma=1$ ). This is in agreement with the equation of Doss and Rao (1938)

$\cos \theta = 2\sigma - 1$ . The derivation of this equation from theoretical considerations is explained. There are no experimental data, however, with which to compare the equation when  $\theta$  is greater than 0 or  $\sigma$  less than 1. C.

## 10—ECONOMICS

**British Cotton Industry: Reorganisation.** The Cotton Board. *Textile Weekly*, 1944, 34, 138-142. A statement on the advantages of amalgamations between firms in the various sections of the cotton trade, and on the extent to which such integration already exists. In spinning, more than half the capacity of the mills is controlled by 31 firms, but in weaving the proportion of small firms is very much larger. In finishing, there are many small concerns, but also a few very large concerns. In the merchant converting section, about 15 per cent. of the total trade is in the hands of the largest ten firms, but the export trade is more concentrated, the largest ten firms controlling 25 per cent. of the business. Only 18 per cent. of spindles and looms are controlled by "vertical" firms. C.

**Textile Wholesale Prices, June, 1944.** *Bd. Trade J.*, 1944, 150, 265. The wholesale price index numbers for June are Cotton, 159.3, Wool 184.0, Other textiles 134.6. C.

**Rayon, Cotton and Wool: Cost of Production.** "*Times*" *Trade and Engineering*, 1944, 55, 43. In 1939 the raw materials for 100 tons of viscose rayon would have cost £2,846 (wood pulp £2,527, sulphur £319). For 100 tons of acetate rayon the costs would have been £1,827 for imported linters, £1,462 for molasses and £72 for sulphur; total £3,361. The corresponding costs for cotton would have been £6,299 and for wool £15,493. C.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY, AND EDUCATION

**Benzole Workers: Poisoning and Control.** R. M. Watrous. *Ind. Med.*, 1943, 12, 721-723 (through *Bull. Hygiene*, 1944, 19, 366). Periodical blood counts are the only safe way of controlling the risk of benzole poisoning. The author has organised a method for carrying out such periodical examinations. First he determines the limits of the normal blood picture; depression of the bone marrow is indicated by either a white cell count below 5,000, or a red cell count below 3,000,000, or polynuclear cells below 30 per cent., or any immature or abnormal red or white cells. Next he places the names of the exposed workers on a list, and enters each monthly examination against the particular name, using a black spot if normal, a blue if suspicious, and red if abnormal. A glance at this list shows whether an undue number of blue and red marks occurs for any month, whether the examinations are being made regularly, and the past blood picture of any individual man. In three years five cases of incipient bone marrow failure were detected; all the patients recovered on removal from contact with the poison. Such removals stimulated superior officers to find and remedy benzole hazards formerly considered unimportant; hence there has not been a single red mark on the list for the year. C.

**Carbon Tetrachloride: Toxic Symptoms.** Alice Stewart and L. J. Witts. *Brit. J. Ind. Med.*, 1944, 1, No. 1, 11-19 (through *Bull. Hygiene*, 1944, 19, 365). Carbon tetrachloride resembles chloroform in possessing anæsthetic properties when administered in heavy concentrations; under such conditions it may produce fatal results due to narcosis, hepatic necrosis or acute nephritis, but, if the victim survives, little or no permanent damage ensues. A survey is presented of 170 men and women working in varying, but at times heavy, contact with carbon tetrachloride. More than half had been discharged or transferred from their employment on account of symptoms attributed to carbon tetrachloride poisoning. These symptoms, due to sublethal concentrations, are gastrointestinal distress and mental hebetude. Complaints made included vomiting in 122 cases, nausea in 110, diarrhoea in 97, abdominal pain in 78, anorexia in 64, vertigo in 21, and weakness in 12. The blood was carefully examined without disclosing any abnormality; barium meals were given, revealing hyper-tonicity, irregular peristalsis and spasmodic contraction of stomach and intestines, and accelerated passage of the meal. The mental symptoms were

sub-narcotic-lethargy and loss of mental agility. No damage to the eyes was found. When withdrawn from exposure all the patients recovered; but they establish that chronic poisoning due to carbon tetrachloride exists. The mental hebetude is ascribed to action on the cerebral cortex, and the gastro-intestinal symptoms to stimulation of the parasympathetic or inhibition of the sympathetic centres in the hypothalamus. C.

**Carbon Tetrachloride Patient: Treatment with Casein Digest and Methionine.** J. Beattie, P. H. Herbert, C. Wechtel and C. W. Steele. *Brit. Med. J.*, 1944, Feb. 12, 209-211 (through *Bull. Hygiene*, 1944, 19, 365-366). A report is given of a case of acute carbon tetrachloride poisoning, following accidental ingestion of 30-40 c.c., which was successfully treated with methionine. The patient was given 2 g. of *dl*-methionine by mouth and later a casein digest-methionine solution was injected intravenously. The infusion was prepared by dissolving 20 g. of a dried papain-trypsin digest of casein in 600 ml. of distilled water, acidifying the solution, adding 15 g. of *dl*-methionine, boiling and filtering. The final pH was 7.6 and the solution was approximately isotonic. Laboratory investigations, indicating the mode of action of methionine, including estimations of the nitrogen and sulphur balances and partition of the urinary sulphur between oxidised (total sulphate) and unoxidised (neutral) fractions, are reported. It is concluded that no actual destruction of liver tissue took place, but that the cause of liver disturbance induced by carbon tetrachloride is the abnormal metabolism of methionine and related compounds. The administration of methionine is considered to have prevented permanent liver damage. C.

**Colour-blind Textile Workers: Employment.** W. Schweisheimer. *Rayon Textile Monthly*, 1944, 25, 175. Colour blindness is explained in popular language from the medical point of view, and it is conceded that men may be trained to match colours even though they may fail to describe them correctly. Tests of abnormal colour vision are mentioned. C.

**Textile Operatives: Raising Efficiency.** *Textile World*, 1944, 94, No. 4, 89-96. An illustrated account is given of schemes for increasing the efficiency of operatives inaugurated by United States Government departments to meet the problems of labour shortage. The separate schemes are (1) Job relations training, with a six-day course for overseers, sponsored by the War Man-power Commission; (2) the Physical fitness programme of the Federal Security Agency; (3) Aptitude tests due to the War Man-power Commission, and (4) the Organization of labour management committees, as advocated by the War Production Board. C.

**Textile Operatives: Training.** J. H. Groves and H. O. Carlton. *Cotton (U.S.)*, 1944, 108, No. 5, 89-92; No. 6, 101-103. The authors describe a scheme for the training of new operatives now followed in some mills in Georgia, under the guidance of the United States War Man-power Commission and the Department of Industrial Education, Georgia School of Technology. An essential feature is detailed analysis of the job. Thus, spinning is analysed into 28 tasks and doffing into 21. Each of these is the subject of a set lesson-demonstration. The lesson about "Cleaning off the scavenger roller," for example, is shown in outline; it takes 35 minutes. A daily schedule for the first week is drawn up. That for the first day allows for 4 hours of general orientation (explaining the objects, the rules enforced by the management, visiting the various departments, etc.) and 4 hours of actual lessons. The operation of the scheme and its advantages are described. C.

**Weavers and Overlookers: Training.** A. Sumner. *Textile Manufacturer*, 1944, 70, 293, 296. Suggestions are made of topics that might be included in the training of weavers and overlookers, with special emphasis on economic and technical aspects. C.

**Women Loom Tacklers: Selection and Training.** A. C. Wayman. *Textile World*, 1944, 94, No. 4, 97, 120. The writer advocates the training of women to do such jobs as setting weft feelers, adjusting the pick, aligning the reed and shuttle boxes, adjusting warp tension, levelling the shafts, adjusting the shuttle check, testing shuttle tension and so forth. On such a plan two women might work with one man to do the routine work on 120 looms, leaving the man (as "head tackler") to do the heavier or more difficult work. The shuttle shop might be staffed entirely by women. C.

**Assam Handloom Weaving Industry: Improvement.** H. K. Nandi. *Indian Farming* 1943, 4, 620-621. Handloom weaving in Assam is by far the most important, valuable and widespread cottage industry and is next in importance to agriculture. Towels, teapoy covers, table cloths, napkins, dhoti, sari, lunji, riha, mekhaia, chadar, shirtings and suitings of various designs, sheets, bed covers, curtain cloth, bandages, etc., are produced. These products find a local market and are sometimes exported to other provinces. The ordinary Assam hand-woven cloth, though it costs much more than the cloth of the same texture produced by power looms, is appreciated because of its lasting quality and artistic style and design. Reasons for the steady progress of the handloom industry and measures that would encourage further development are outlined. The Department of Industries maintains two weaving schools for the training of students, two emporiums for the supply of looms, accessories, yarns, dyes and chemicals, and 40 peripatetic weaving demonstrators in important centres for training weavers in improved methods of weaving and yarn preparation and for circulating new designs. In addition to cotton weaving, a good deal of silk weaving is done in the province. C.

**Textile Mill Time Studies: Conduct.** Osbert Hughes. *Cotton* (U.S.), 1944, 108, No. 3, 90-93. Practical hints are given on the purposes and conduct of time studies of textile operations. For the purpose of fixing a normal rate of production it is not advisable to do a limited number of observations on an "average" operative but to assess the "speed rating" of a number of operatives and correct the observed times to one standard. Thus, if in the considered opinion of the observer an operative is rated as, say, a "105 per center," the observed times for her tasks would be multiplied by 105/100. These corrected times are then averaged over a number of operatives (weighted means are recommended) and the results are posted on a sheet called the "Master Element Summary." As an example, the sheet for the task of creeling one bobbin of roving is reproduced. This bears the machine and other spinning particulars and a summary of the various time studies; the final average—or "selected standard time" for the job—is 0.444 minute. C.

**Park High School, S. Carolina: Organisation.** Loui Greet. *Cotton* (U.S.), 1944, 108, No. 3, 87-9, 116; No. 4, 106-108. An illustrated account is given of the development in the Parker School District, Greenville, S. Carolina, of textile training at the High School and of courses for adult operatives. C.

**Textile Industries: Educational Reconstruction.** G. D. H. Cole. *J. Textile Inst.*, 1944, 35, P51-60. C.

**United States National Bureau of Standards: Textile Activities.** W. D. Appel. *Amer. Dyes. Rept.*, 1944, 33, 182-184. A report of an address on the general functions and organisation of the National Bureau of Standards and its special work in the fields of textile testing and standardisation. C.

**Institute of Textile Technology: Organisation.** *Textile World*, 1944, 94, No. 5, 113. A list is given of the officials and trustees of a new Institute of Textile Technology, established at Charlottesville, Virginia, U.S.A. The plan is to accept 15 science graduates each year and train them in textile research at the feet of 7 or 8 teachers who are recognised textile technologists and scientific workers. Specific researches will be undertaken for members on a "cost plus" basis. The Institute will maintain a library, and issue a monthly digest of the literature and a quarterly research bulletin. C.

**Colour and Eye Strain.** F. Birren. *Ldy. & Dry Cleaning J. of Canada*, 1944, June, 20, 32. Eye strain is stated to be responsible for general deterioration in health and consequently in output and sometimes it may lead to serious bodily complaints. Colour can play a very important part in the relief of eye strain in industry and there is room for considerable research to find the ideal conditions for comfort and production. La.

## ABSTRACTS

### 1—FIBRES AND THEIR PRODUCTION

#### (B)—ANIMAL

**Wild Silk Cocoon: Processing.** N. S. Simonov. *Tekstil. Prom.*, 1941, No. 5, 41-44 (through *Chem. Zentr.*, 1943, i, 230 and *Chem. Abstr.*, 1944, 38, 3138<sup>s</sup>). The wild silk worm, *Antheraea pernyi*, is cultivated in the oak forests in various sections of the U.S.S.R. Details of the treatment of the cocoons are discussed.

C.

**What Should a Sire's Wool Look Like?** E. H. B. Lefroy. *Pastoral Rev.*, 1944, 54, 196-197. Observations are made on the fineness and crimp of the merino staple.

W.

**Merino Sheep: Future.** *Pastoral Rev.*, 1944, 54, 195-196. A discussion of threats to the future of the merino, local dangers in Australia being the long-distance one of closer settlement of land, and the immediate one of losses due to the blowfly. The chemical production of synthetic fibres is the newest and most threatening danger to wool of all types.

W.

**Wool Classing: Evils of Over-classing.** "Jason." *Pastoral Rev.*, 1944, 54, 76-78. The tendency to make too many grades in classing has been stimulated by the fact that under the current Imperial Purchase Scheme the Table of Limits has been extended to 3,000 types of wool.

W.

**The Auchenia of South America.** E. Mascheroni. *Internat. Rev. Agric.*, 1941, 32, 134T-142T (through *Animal Breeding Abs.*, 1944, 12, 97). The habitats and economic uses of the llama, alpaca, vicuna, guanaco and their chief cross-breeds are described, and details given of fleece characteristics.

W.

#### (C)—VEGETABLE

**Punjab-American 4F Cotton: Effect of Irrigation.** M. Afzal. *Indian J. Agric. Sci.*, 1943, 13, 357-367. An account is given of investigations of the effects of seven different types of irrigation on the field behaviour and quality of Punjab-American 4F cotton. Flowers and bolls produced per plant were not correlated with the quantity of water given to the crop but, in general, the yield was correlated with watering. Ridging gave indifferent results compared with flat sowing. Application of more water during the growing period is likely to improve, to a small extent, the mean fibre length. The amount of irrigation applied to the crop did not produce any significant effect on either the mean fibre weight per inch or the standard hair weight of this cotton. The percentage of mature hairs showed a tendency to increase with the amount of water applied to the crop. The spinning performance of the cotton showed a small tendency to improve as more water was given to the crop.

C.

**Punjab-American 289F/43 Cotton: Variations in Quality.** S. Rajaraman and M. Afzal. *Indian J. Agric. Sci.*, 1943, 13, 349-356. To study the effect of date of sowing on the quality of lint of Punjab-American 289F/43, sowings were carried out in 1937 in randomized blocks with seven replications. The dates of sowing were: (1) 15 April, (2) 5 May, (3) 20 May, (4) 4 June and (5) 1 July. The third and fourth sowings were within the range of general agricultural practice, the second was slightly earlier, the first too early and the fifth too late. The lint produced in each of the sowings was tested for mean fibre length, modal length, fibre-length irregularity, mean fibre weight per unit length, percentage of mature fibres, and highest standard warp counts. The second, third and fourth sowings yielded lint of the same quality and definitely better than that from the first sowing. The pickings from the fifth sowing were on the

whole similar in quality to corresponding pickings from the second, third and fourth sowings, but the lower percentage of mature fibres and consequent nepiness would detract from the quality of the yarn. Variations in lint quality with progressive pickings were also observed. C.

**Sea Island Cotton: Cultivation in U.S.A. (Georgia).** J. G. Jenkins. *Georgia Coastal Plain Sta. Bul.*, 33, 1942, 21 pp. (through *Exp. Sta. Rec.*, 1943, 88, 188). Cultural and field practices and harvesting, ginning, and boll weevil control methods involved in growing Sea Island cotton are described, with comments on marketing the crop. Emphasis is placed on planting pure seed, its maintenance and distribution, roguing seed fields, and advantages of one-variety communities in maintaining purity. Dosages for seed treatment are recommended, and a home-made treater is illustrated. C.

**Cotton Seeds: Germination; Effects of Soil Disturbance and Fertilizer Placement.** H. P. Smith, M. H. Byrom and H. F. Morris. *Texas Sta. Bul.* 616, 1942, 29 pp. (through *Exp. Sta. Rec.*, 1943, 88, 328). Effects of machine placement of fertilizer and of soil disturbance on the germination of cotton seeds were studied in 1936-40. The best germination and emergence were obtained when seeds were planted on a firm, undisturbed soil, and better stands were obtained with fertilizer placed 2 in. to the sides of the seed and 1 or 2 in. below the seed level. The highest yield was obtained at College Station when fertilizer was placed 2 in. to each side and 1 in. below seed level and at Nacogdoches when fertilizer was placed 2 in. to each side and 2 in. below the seed level, although fertilizer applied in any manner significantly increased yield at both stations. C.

**Boll Weevil: Hibernation, Survival and Emergence.** F. F. Bondy and C. F. Rainwater. *J. Econ. Entomology*, 1942, 35, 495-498 (through *Exp. Sta. Rec.*, 1943, 88, 368). Studies are reported of the factors that influence the abundance of the boll weevil, with particular reference to hibernation, survival, and emergence, conducted in the vicinity of Florence, S.C. They included cage tests, examination of Spanish moss and woods trash, and trap-crop emergence. C.

**Cotton: Ginning; Costs in North Carolina.** S. L. Clement. *North Carolina Sta. Tech. Bul.* 71, 1942, 23 pp. (through *Exp. Sta. Rec.*, 1943, 88, 402). The ginning industry is described. Data for 63 gins for the 1940-1941 season are analysed to show the average cost per bale for different items of ginning expense, the frequency distribution of gins on the basis of average cost per bale, and the relationship of volume of ginning and number of gin stands to ginning costs. The number of active gins in the State declined from 2,625 in 1914 to 824 in 1940, but the number of bales per active gin almost doubled. The average number of saws per gin increased from 80 in 1906 to 211 in 1940. The cost of ginning per bale in the 63 gins studied ranged from \$2.42 to \$6.54, averaging \$3.16. The average costs for different items were: Administration 42 cents., ginning labour 55, repairs and upkeep 18, power and fuel 38, bagging and ties 81, and depreciation 46 cents. Average costs per bale declined as the number of bales increased up to 1,501-2,000 bales. Some relationship was found between ginning costs and the fee charged the grower for ginning. The estimated average receipts per bale from ginning fees, assuming fees were collected for all bales ginned, were \$3.37, being 21 cents in excess of the average costs of ginning. The costs were in excess of the estimated receipts for approximately 43 per cent. of the gins. C.

**South Carolina Ginning Services: Quality.** J. M. Stepp and H. A. White. *South Carolina Sta. Bul.* 344, 1942, 15 pp. (through *Exp. Sta. Rec.*, 1943, 88, 402). Data for 1941 were obtained by a survey of 49 gins located in 20 counties of the State. Some of the findings were: Of 29,392 bales ginned by the 49 gins 8.4 per cent. were reduced one or more grades because of gin damage. Ten per cent. of the gins accounted for 47 per cent. of the gin-damaged cotton, and one-fifth of the gins for two-thirds of the damaged cotton. A high percentage of rough ginning was done in gins operated by merchants and a low percentage in those operated by oil mills. There was no consistent relationship between experience of gin managers and quality of ginning. Experience of the ginner and quality of ginning were related. The gins with the highest and lowest volumes of output had the lowest percentage of gin damage. In general, there was a relationship between, age of gin

stands and quality of ginning. Gins with driers usually did the better ginning. The relationship between cleaning equipment and quality of ginning was not so obvious. C.

**Indian Sunn-hemp: Production; Processing and Grading.** N. Das and B. P. Bhargava. *Indian Farming*, 1943, 4, 505-507. The plant *Crotalaria juncea*, from the stems of which the sunn-hemp fibre is extracted, is a shrubby annual, usually about 4-7 ft. high. The plants are either pulled out by the roots or the stems cut close to the ground. They are then stripped of leaves, tied in bundles and subjected to retting. After retting the fibre is extracted by various methods. Further processing consists either in simply cleaning the fibre by striking bundles against wooden boards fitted with long iron spikes or in dressing or hackling. The several types of sunn-hemp grown in different parts of India show differences in respect of colour, strength, length of fibre, extent of tangling, amount of impurities, etc., and are marketed under a number of trade descriptions. The annual yield of fibre is roughly estimated at 80,000 to 100,000 tons. The fibre finds considerable use in the villages for cordage, mats, etc., and is also exported. Figures are given showing the vicissitudes of the export trade during the last 20 years. Recommendations for improving the quality of Indian sunn-hemp and Government Grading and Marking Rules are outlined. C.

**Mulberry Fibre: Characteristics.** H. Höfer. *Faserforschung*, 1941, 15, 49-77 (through *Chem. Zentr.*, 1943, i, 230 and *Chem. Abstr.*, 1944, 38, 3135<sup>3</sup>). *Morus alba* is important as an additional source of raw material for the textile industry. The fibre is equal in many respects to cotton, and superior in some respects. It is white and soft, and has a silky feel and good strength; average length is 2.5 cm. Technological problems of recovering this fibre from the plant have not yet been solved completely. C.

#### (D)—ARTIFICIAL

**Casein: World Supplies.** *Silk & Rayon*, 1944, 18, 999. The prospects of adequate supplies of casein for rayon after the war are reviewed and held to be very uncertain. Production and export figures for 1935-1938 are tabulated. They show that exports were declining in all countries but the Netherlands. C.

**Cellulose Pulps: Sources and Preparation.** H. Jentgen. *Kunstseide u. Zellwolle*, 1942, 24, 350-364 (through *Chem. Zentr.*, 1942, ii, 2222 and *Chem. Abstr.*, 1944, 38, 2818<sup>9</sup>). The following sources have come into greater use for pulping: beechwood, fast-growing poplars, straw, potato tops, flax and hemp chaff, reeds, millet, broom, esparto, rice straw, corn stalks and soybean straw. Pulping methods developed in different countries and experiences with them are described. The new Kelheimer method can be made fully continuous. Illustrations of some newer plants are reproduced. C.

**Fish Protein: Behaviour in the Manufacture of Animalized Fibres.** O. Mecheels and K. A. Essig. *Zellwolle, Kunstseide, Seide*, 1941, 46, 167-172 (through *Chem. Zentr.*, 1941, ii, 1231 and *Chem. Abstr.*, 1944, 38, 2825<sup>9</sup>). Fish protein is not uniform in its solubility in alkalis; it is more resistant than casein towards alkali degradation and the action of viscose. The protein is dispersed after some time by the viscose. At a ripening temperature of 25° the protein is degraded by the viscose; at temperatures below 6° such degradation by the viscose could not be detected. A new process is described for sulphiding the alkali-pretreated protein by means of carbon disulphide to effect thorough distribution of the protein in the viscose. The loss of protein during the manufacture of fibre is due to alkali soluble particles that cannot be precipitated by the precipitation bath, to degradation of the protein in the viscose with the formation of non-precipitating products, and to filtration losses resulting from insufficient distribution of the protein. No filtration losses and no degradation by the viscose even at normal ripening temperatures (25°) could be detected with sulphided protein preparations. The lowest protein losses were obtained by the introduction of unhydrolysed proteins into the viscose or by the admixture of sulphonated protein preparations. Tables, photo-micrographs and curves are shown. C.

**Rayon Cellulose: Removal of Pentosans.** E. Lindpaintner. *Textilberichte*, 1942, 23, 229-230 (through *Chem. Abstr.*, 1944, 38, 2819<sup>2</sup>). For rayon manufacture it is recommended that the concentration of residual pentosan of the

cellulose used should be not more than 2-4 per cent., and that there should be present a minimum quantity of low-polymer celluloses of polymerisation degree about 150. The pentosan can be extracted without great loss of yield by the action of cold aqueous 6-10 per cent. caustic soda. The optimum conditions, however, vary considerably, and depend on the strength of the cellulose-pentosan linking, the distribution of the links in the chain system, the polymerisation degree of the celluloses present, and the influence of the structure and morphology of the native fibre; in particular, the time of treatment depends to a considerable extent on the thickness of the fibres treated. Yield and residual pentosan data are presented for a wide range of extraction conditions for bleached pulps made from beech, spruce (sulphite), hemp (sulphate), hop pulp, *Phragmites* reeds, and potato haulm (soda process). Cold refining with alkali after digestion and bleaching is preferable to intensive cooking processes for reduction of pentosan content. C.

**Rayon Liquors: Filtration.** A. Meyer. *Zellwolle, Kunstseide, Seide*, 1941, 46, 172-174 (through *Chem. Zentr.*, 1941, ii, 1231 and *Chem. Abstr.*, 1944, 38, 2818<sup>a</sup>). For rayon and staple fibre manufacture, a fine fibrous acid- and alkali-resisting material suspended in the liquid is caused to build up a filtering layer. It is suitable for the filtration of mercerizing liquors, precipitation baths, after-treatment liquors, etc. C.

**Nylon Yarn: Production and Properties.** G. Loasby. *Chemistry and Industry*, 1944, 282-283. A report of a lecture tracing the history of nylon production, the properties of current nylon yarns, and their winding, sizing, scouring and dyeing. C.

#### PATENTS

**Rayon Staple Liquid Treatment Apparatus.** British Celanese Ltd. B.P. 563,168 of 15/5/1942:3/8/1944 (Conv. 17/5/1941). An apparatus for treating fibrous materials with liquids comprises a trough, a band passing along the bottom of the trough to convey the material, and a roller to compress the band and its load of fibrous material against the bottom of the trough and to allow the compressed material to expand into the liquid medium in the trough. Preferably, after the fibres have been treated for a sufficient time they are carried by the band under a second roller by means of which the liquid is squeezed out as the material emerges from the liquid. The roller or rollers thus provided in the trough may conveniently be adapted to retain the liquid medium in the trough. The band is preferably in the form of an endless apron, perforated to allow the liquid medium to pass through the band and reach the fibres. C.

**Rayon Thread Guiding and Liquid Treatment Apparatus.** Lustrafil Ltd. and S. W. Barker. B.P. 563,296 of 4/1/1943:8/8/1944. A roller device for the guiding and liquid treatment of rayon threads is provided with one or more interrupted ribs or grooves for the purpose of confining each liquid treatment to a definite zone on the roller. Preferably, the interrupted ribs or grooves are disposed at least in pairs, the gaps being spaced diametrically opposite to one another. The interruptions in the ribs may be inclined at an angle to the axis of the roller and may be bevelled or chamfered on one side. The flanges or grooves may have more than one interruption if desired, although normally one will be sufficient. C.

**High-frequency Electric Filament Drying and Crimping Apparatus.** American Viscose Corporation. B.P. 563,440 of 30/3/1943:15/8/1944 (Conv. 10/4/1942). Apparatus for drying, crimping or otherwise treating filamentary material comprises an insulating belt for conveying a layer of fibre, a second belt having a course engaging the upper surface of the layer, means for moving the adjacent courses of the belts at substantially the same velocity and means for subjecting the material between the belts to a high-frequency electric current, supplied to a pair of electrodes, one beneath and the other above the adjacent courses of the belts. Alternatively the second belt may be of electrically conductive material, the high frequency electric current being supplied to the belt and to an electrode beneath the insulating belt. The belts may both be of elastic material, the apparatus comprising a number of pairs of rolls and means for driving each succeeding pair of rolls at a speed of rotation less than that of the preceding pair, whereby the filamentary material is crimped. The apparatus may be enclosed in a substantially gas-tight chamber, means being provided for withdrawing gases and vapours from the chamber. C.

**Alkali-treated Cellulose: Dehydration.** British Celanese Ltd. B.P.563,560 of 16/11/1942:21/8/1944 (Conv. 15/11/1941). Cellulose which has been swollen by treatment with alkali and then washed free from alkali by means of water is dehydrated by removing the water as an azeotropic mixture with an organic compound. In a preferred procedure the swollen cellulose is first pressed or centrifuged to remove most of the water and then distilled with ethyl acetate, nitromethane, propyl or butyl acetates or alcohols. Cellulose which has been treated in this way has an enhanced reactivity and is particularly useful for conversion into cellulose esters. C.

**Rayon Cakes: High-frequency Drying.** G. M. Clark (Radio Corporation of America). B.P.563,590 of 24/11/1942:22/8/1944. A process of drying rayon in cake form comprises subjecting the cake simultaneously to at least a partial vacuum and to the action of a high-frequency electric field. Optimum results are obtained by using a vacuum of about 29 in. of mercury and a frequency of about 25 megacycles. C.

**Rayon Staple Liquid Treatment Apparatus.** American Viscose Corporation. B.P.563,630 of 3/11/1942:23/8/1944 (Conv. 12/11/1941). Apparatus for the liquid treatment of rayon in successive stages comprises perforate means for continuously conveying the material through a path, spray means above the conveyor for applying liquid to the material along one or more portions of the path, means for elevating a portion of the conveyor in advance of and beyond each portion of the path where the liquid is applied to confine the liquid applied and to prevent its flowing along the conveyor, and means, e.g. a suction box, below the conveyor for drawing the liquid through the fibrous material. C.

**Spinneret.** Baker & Co. Inc. (Newark, New Jersey, U.S.A.). B.P.563,648 of 28/8/1942:4/8/1944 (Conv. 26/7/1941). A spinneret is made of an alloy of platinum, rhodium and ruthenium containing 1-15 per cent. Rh and 0.5-10 per cent. Ru. Such a spinneret shows high resistance to abrasion, mechanical deformation by pressure, and chemical attack by viscose and by acid coagulating baths. In addition clogging of the orifices is less than with the usual types of spinnerets. C.

**Viscose: Production.** E. I. Du Pont de Nemours & Co. U.S.P.2,338,196. Cellulose xanthate and caustic soda solution are mixed in the desired proportions and stirred to a slurry. A stream of this slurry is beaten into particles and thrown against an apertured surface until a uniform viscose composition is formed. C.

**Superpolyamides of Stable Viscosity.** H. Kroeper, F. Kohler and K. Wolf (Heidelberg; vested in U.S. Alien Property Custodian). U.S.P.2,338,443. The equimolecular mixture of diamine and dicarboxylic acid for condensation to a superpolyamide contains up to 20 per cent. of the hexamethylenediamine salt of glutaric acid, the main bulk of the dibasic acid being a different acid. The superpolyamide is claimed to be stable in viscosity. C.

**Centrifugal Glass Fibre Spinning Apparatus.** G. von Pазsiczky (Hamburg; vested in U.S. Alien Property Custodian). U.S.P.2,338,473. Apparatus for spinning relatively fine glass fibre comprises a cylindrical receptacle for molten glass, openings through the vertical wall at opposite ends of a diameter, and a gas burner fed at high pressure through the axle, with two branches ending in nozzles in the openings. The receptacle and burner are rotated at high speed and the glass is spun into filaments through the combined action of centrifugal force and the blast from the burner. C.

**Electrostatic Cellulose Acetate Spinning Device.** Eastman Kodak Co. U.S.P.2,338,570. A solution of cellulose acetate in acetone at 40-70° C. is forced through an orifice, 0.035-0.15 mm. diam., in a dielectric material, under the influence of a high tension field. C.

**Lustrous Cellulose Ester Filaments: Production.** Eastman Kodak Co. U.S.P.2,338,641. A solution in a volatile solvent containing 1.5-2.5 per cent. of water and at least 25.5 per cent. of a hydrolyzed cellulose ester (soluble in acetone) containing 1-6 per cent. of saturated fatty acid groups of 3-4 C atoms, the remainder being acetyl, is spun in hot air at a speed of at least 450 metres per minute. The ester is specified as having a viscosity of 30-150 seconds for a solution of 1 part ester to 4 parts acetone. C.

**Skin Wool: Cleansing.** R. Gutensohn (to I.G. Farbenind. A.-G.). D.R.P. 715,441 of 27/11/1941 (through *Chem. Abs.*, 1944, 38, 2218). Skin wool is treated in an acid liquor containing organic acids combined with suitable buffers, condensation products of  $\alpha$ ,  $\beta$ -alkylene oxides and high molecular aliphatic alcohols or alkylphenols and aminocarboxylic acids containing more than 1 carboxyl group in the  $\alpha$ -position of the N. W.

## 2—CONVERSION OF FIBRES INTO FINISHED YARNS

### (A)—PREPARATORY PROCESSES

**Card Web: Photo-electric Measurement of Irregularity.** A. Varga and N. H. Chamberlain. *J. Textile Inst.*, 1944, 35, T89-92. C.

### (B)—SPINNING AND DOUBLING

**Casablancas Two-zone Drafting System.** F. Wooding. *Textile Weekly*, 1944, 34, 267-270. A drawing is given of a high-draft system with a back zone consisting of two lines of fluted steel bottom rollers and two lines of cushion-covered top rollers and a front zone consisting of the Casablancas "apron-cradle" system. The writer reports favourably on a trial of the system over a period of some weeks, on a Howard and Bullough roving frame with 7-in. lift. The best results were obtained when the draft in the front zone was about four times the draft in the back zone and a slight "creep" draft was secured between the zones. C.

**Rayon Staple: Spinning.** H. Ashton. *Textile Weekly*, 1944, 34, 440, 446. Particulars are given of the commercial limits of count to which various marks of "Fibro" staple can be spun on (a) cotton, (b) worsted, (c) woollen and (d) waste condenser systems, and also of the hank numbers, drafts, speeds and settings recommended at various stages in the production of 32s from 1½-in., 1.5 den., bright "Fibro." Hints are given of the probable influence on machine design of the introduction of "Greenfield tops." C.

**Rings and Travellers: Recent Developments.** D. Eadie. *J. Text. Inst.*, 1944, 35, P65-69. C.

### PATENTS

**Up-twister Throwing Machine Yarn Tensioning Device.** H. Lasch. B.P. 563,241 of 16/10/1942:4/8/1944. In an up-twister throwing machine, the yarn coming from the supply package and flyer is caused to pass through two movable guides arranged to give it a substantial deflection, one of which functions as a balloon guide, the relative positions of the guides (and therefore the amount of deflection in the yarn) being determined by the tension in the yarn against the influence of counter-weight means, increase of tension causing less deflection in the yarn and also resulting in a lowering of the balloon guide so as to shorten the balloon and relieve the tension in the oncoming yarn, whilst decrease of tension has the opposite effect. In a typical machine the usual fixed balloon guide is replaced by a pivotally-mounted balloon guide, and a further pivotally-mounted guide substantially deflects the yarn between the balloon guide and the glass rod, both guides being overbalanced by a common counter-weight, but being capable of yielding under any increased tension of the yarn. The second guide yields to lessen the degree of deflection in the yarn and thus allow a short extra length to go forward to relieve the increased tension in the yarn where it originated, and the balloon guide yields to reduce the tension again, back to normal, by moving towards the supply package. C.

**Nasmith Combing Machine.** G. W. Nasmith, J. I. Nasmith and District Bank Ltd. B.P. 563,282 of 30/10/1942:8/8/1944. In a Nasmith combing machine the usual combing cylinder segment is dispensed with and there is provided a guide plate which rises and falls in a path between the detaching roller position and the combing cylinder cover, the movements of such plate having the necessary synchronism with the movements of the detaching rollers, nipper, and top comb to engage by contact, and thus guide and control, the end of fleece backed off for piecing in and throughout its movements in both directions. The guide plate rises to its uppermost position to receive the end of the fleece as it begins to be backed off, descending with the fleece, then rising therewith and dwelling during the rise until the top comb has commenced to withdraw and then again resuming its uppermost position. The fleece end is

thus never in contact with a surface moving in the opposite direction to itself, and incidentally, the use of the cylinder segment being discarded more effective cover may be provided for the dangerous needles. C.

**Synthetic Rubber Roller Cover.** J. Rockoff (Dayton, Ohio, U.S.A.). B.P. 563,374 of 28/9/1942:11/8/1944. A cot or cover for a roller of a spinning or other textile machine consists of a vulcanized synthetic rubber composed of butadiene-acrylic nitrile co-polymer, a filler, a resin, dibenzyl ether and benzothiazyl disulphide. Cots of this type have a smooth, dry surface, do not develop gumminess on prolonged running and are tough, resilient, and resistant to oxidation, abrasion, and oil. C.

**Draft Roller Gearing Guard.** J. and L. Gleave. B.P.563,693 of 6/4/1943:28/8/1944. A guard for the draft roller gearing of ring spinning frames comprises an arm provided on the starting rod and connected to a catch lever mounted on the spinning frame at one side of the headstock and adapted in one position to secure the hinged guard cover of the gearing at the said side, the lever being tied by a tie bar to a second catch lever mounted on the spinning frame at the opposite side of the headstock and adapted in one position to secure the hinged guard cover of the gearing at the opposite side. Means are provided on the guard covers to prevent movement of the levers in one direction while the covers are open and thereby prevent starting of the ring spinning frame while the covers are open. These means may comprise bent bars secured to the covers and adapted in the open position of the guard covers to lie in the path of the tie bar and thereby prevent the tie bar and therefore the starting rod from rotating into the starting position. C.

**Wet Spinning Machine.** W. Gibson. B.P.563,863 of 5/2/1943:1/9/1944. A spinning, twisting or like machine and especially a wet spinning machine is provided with a spindle to support detachable yarn packages, a yarn laying-on member for traversing the yarn and building the pirn, comprising yarn guiding-on means at its upper edge, a lower part below the guiding-on means rotatably mounted in a bearing for the spindle so that in operation the maximum unsupported length of spindle does not substantially exceed the length of the building traverse, and a recess for accommodating the yarn receiving means in the lower part extending downwardly a sufficient distance from the guiding-on means to permit of laying-on being commenced at the top of the pirn receiving means. The laying-on member comprises an upper part which is preferably of frusto conical shape to accommodate the tapered end of the pirn during the building traverse and has yarn guiding-on means at the upper edge thereof and a lower part which has a pirn tube recess extending down from the cupped part a sufficient distance to permit of laying-on being commenced at the top of the pirn and has an inner cylinder whose outer surface forms the inner surface of the recess and a bearing or guide surface for the pirn tube and whose inner surface forms a bearing means of substantial length for the spindle up to near the level of the guiding-on means. Preferably the pirn tube and spindle have a detachable connection which causes them to rotate together, but which permits the tube and fully formed pirn automatically to be doffed or detached from the spindle and left sitting on the upper or cupped part of the laying-on member when the spindle is lowered to the starting position. C.

**Ring Frame Builder Motion.** Saco-Lowell Shops (U.S.A.). B.P.563,898 of 16/6/1942:5/9/1944 (Conv. 28/8/1941). A builder motion for a ring spinning frame of the kind comprising initial driving means for imparting a straight line motion to a primary element, mechanism for transmitting from the primary element a linear motion to the ring rail, means for reversing the straight line motion imparted to the primary element, two means for determining the positions of the points at which such reversals take place, at least one of such means being progressively adjustable to vary the position of reversal controlled thereby, and power driven mechanism for actuating the adjustable means for varying the position at which reversal takes place while the spinning operation continues is characterised in that adjustable controlling means is provided for the power driven actuating mechanism of the adjustable means such that the extent of the adjustment movement of the adjustable means at each progressive adjustment thereof can be controlled. The con-

trolling means may also be adapted to control the direction of the adjustment movement of the adjustable means. C.

**Air-blast Lap Treatment Apparatus.** Proctor and Schwartz, Inc. U.S.P. 2,338,619. Loose fibre is conveyed on a foraminous belt under a succession of slots through which sheet-like blasts of air are directed against the fibre. Directly under the blast the fibre is compressed against the travelling surface but laterally the fibre is lifted high and opened. C.

**Hollow Spindle Yarn Plying Machine.** Eastman Kodak Co. U.S.P. 2,338,656. The machine combines a rotating hollow spindle, a spool carrying a core thread arranged to pass through the spindle, a supply of low-twist yarn mounted on the spindle, means for plying the two yarns together, an adjustable brake shoe that engages the spool and imposes tension on the core thread, and means for controlling this tension comprising a flange on the spindle having a diameter at least 25 per cent. greater than the maximum diameter of the package of low-twist yarn. C.

### 3—CONVERSION OF YARNS INTO FABRICS

#### (A)—PREPARATORY PROCESSES

**Winding Machines for Doubling Industry.** Universal Winding Co. *Textile Recorder*, 1943, 61, November, 33-35; December, 40, 47; 1944, January, 48-51; February, 48-50; March, 52-55. An illustrated account of modern machines and methods of winding for doubling. (1) Production tables are provided for the No. 50 "Leesona" cheese winding machine. (2) The importance of large package supply is emphasised, single-end and bunch knots are discussed, and single-end and two-end winding are compared. (3) The No. 44 "Leesona" Roto-coner high-speed winding machine for cones and cheeses, and its output are discussed. (4) The "Dual process" of winding by the "Leesona" Roto-coner and No. 60-GF. multiple-end winding machine are described. (5) The Andrew and Langstreth disc doubler is described and an account is given of the "Universal" No. 5-19 machine which is used to feed the doubler. C.

**Yarns: Preparation for Weaving and Knitting.** *Textile Weekly*, 1944, 34, 225-231. Modern practice in warp and weft preparation is summarised in a series of schemes that indicate the various stages from the mule cop or ring bobbin for typical warps and cloths, and mention is made of the special machines in use. C.

#### (B)—SIZING

**Cellulosic Sizes: Application.** C. Müller. *Deut. Textilwirt.*, 1942, 9, No. 15-16, 23-24 (through *Chem. Zentr.*, 1942, ii, 2220 and *Chem. Abstr.*, 1944, 38, 3139<sup>b</sup>). Sizes made from cellulose can be used for all textiles without the addition of fats. Experiments have been made on the use of unsized yarns. Weaving tests are discussed. C.

**Textile Sizes: Properties and Applications.** I. Madlung. *Kleppig's Textil-Z.*, 1943, 46, 160-163 (through *Chem. Zentr.*, 1943, ii, 90-91 and *Chem. Abstr.*, 1944, 38, 3139<sup>b</sup>). Wheat, rice, potato, and corn starches are particularly suitable for cotton; these may contain water-absorbing, antiseptic or weighting agents. The use of the following products is discussed: vegetable and pectin sizes (e.g. Dorma size) as additions to starch; glue, protein degradation products and gelatin for wool, staple fibre and rayon; linseed oil sizes for rayon; various new cellulose derivatives such as Tylose TWA 25 and 600, Tylose MGC, and Tylose KZ<sub>5</sub> and 25 for staple fibre and rayon; and completely synthetic products of the type of Plexileim. Methods of detecting the various kinds of sizes are described. C.

#### (C)—WEAVING

**"Bracewell" Automatic Weft-replenishing Device.** J. H. Strong. *Textile Mercury & Argus*, 1944, III, 221-225. Drawings are reproduced of a weft-replenishing motion that can be fitted readily to the ordinary overpick Lancashire loom and combines the features of shuttle-changing and pirn-changing automatic looms. It comprises a 4-shuttle circular box which rotates a quarter-turn to bring a fresh shuttle into action when required and the empty shuttle is replenished from a pirn magazine. C.

**Butterworth and Dickinson Silk and Rayon Loom.** J. W. Hutchinson. *Silk & Rayon*, 1944, 18, 1002-1003. A brief description is given of the various special features of a 16-shaft negative dobby loom for silk and rayon weaving. C.

**Centre Weft Fork: Maintenance.** *Textile Recorder*, 1944, 61, July, 58-60. Details are given of the working parts of the centre weft fork, their adjustment and advantages. C.

**Double-lift Jacquards: Setting and Timing.** *Silk & Rayon*, 1944, 18, 886-889. A detailed description is given of the head motion and cylinder operation of the Dracup double-lift jacquard and the settings and timings are fully explained. A suitable varnish for the harness bands consists of starch  $2\frac{1}{2}$  lb., glue  $2\frac{1}{2}$  lb., white soap 2 oz. and potassium carbonate 1 oz. to 15 gallons of water. C.

**Jacquard Looms: Application.** H. Hardaker. *Textile Weekly*, 1944, 33, 326-9, 638-640. A broad review of the art of jacquard weaving and the development of the mechanism, with special reference to the single-life jacquard made by Messrs. John T. Hardaker Ltd., Bradford. C.

**Loom: Overlooking.** *Textile Recorder*, 1944, 61, April, 38-40. Practical hints are given on the early detection by the weaver and overlooker of weaving mistakes. C.

**Silk Fabrics: Weaving.** J. W. Hutchinson. *Silk & Rayon*, 1944, 18, 776-777. Practical hints are given on defects in weaving silk, and remedies for them. C.

**Hand- and Power-woven Wool Fabrics.** (1) I.L. *Text. Mfr.*, 1944, 70, 100, 110. (2) G. Appleyard. *ibid.*, 247. (3) I.L. *ibid.*, 247. (1) In an article appraising the difference between hand- and power-woven fabrics (this *J.*, 1943, 34, P133) no mention is made of templing. On the ordinary hand-loom with no take-up motion, variation of picks per inch occurs when using the ordinary hand-loom temples, illustrations of which are given. The softer handle of both warp and weft in hand- as compared with power-woven fabrics is due to the gentler treatment of the yarn in the preparatory processes and to the fly-shuttle picking of the weft. (2) Templing was not used on the hand-loom for the weaving of the experimental fabrics described in this *J.*, 1943, 34, P133. The differences between professional and amateur hand-loom weaving are discussed. (3) Templing is of major importance in hand-loom weaving, the efficiency of its functioning directly influencing the required strength of the beat-up and thus affecting the entire width of the fabric. Professional hand-loom weavers do not necessarily use such mechanical aids as take-up motions, objections to which are listed. W.

**Wool Weaving Machinery.** L. Bellwood. *Text. Weekly*, 1944, 33, 992, 994-996, 34, 18, 20. Present and future problems connected with the efficiency of automatic looms are discussed, with special reference to cloth construction, time lost by stoppages from various causes (warp and weft renewal, cloth removal, loom repairs), measuring and recording weaving efficiency, and the influence of the human factor. W.

#### (G)—FABRICS

**Crêpe Fabrics: Designing.** *Textile Mercury & Argus*, 1944, III, 173-177, 249-250. Practical hints are given on the construction of crêpe fabrics, with point-paper drafts of typical weaves. C.

**Jacquard Fabrics: Designing.** *Textile Weekly*, 1944, 34, 232-235, 272-274, 406-410. The processes of transferring a design to point paper and cutting and lacing the pattern cards are described with details of the mechanism employed. C.

**Laminated Fabric Plastics: Development and Uses.** C. S. Jones. *India-Rubber J.*, 1944, 107, 177-178. A brief review is given of the probable outlets for cotton cloths (4 oz. to 4 lb. per yard), paper, rayon yarns, and carded and combed cotton webs in the manufacture of low-pressure laminates. Problems for investigation are (1) the production of a cotton fabric with minimum warp crimp and capable of stretch in the weft direction only, and (2) the improvement of fabrics for laminates by blending cotton with other fibres, e.g. glass, or by impregnating them with plastics. C.

## PATENTS

**Shuttle Peg Mounting.** C. Allsopp and G. Newsome. B.P.563,217 of 14/1/1943:3/8/1944. The upper side of a shuttle at the butt end of the peg is provided with a recess to receive a trough-shaped or U-shaped piece of metal having a flat base and vertical sides. In the base of the trough there is provided a U-shaped leaf spring, one leg of which rests flatly upon the base of the trough, whilst the other extends normally either parallel to the base or upwardly at a small angle. The shuttle peg is carried by an L-shaped metal block fitted between the walls of the metal trough. Advantages of the device are that the relatively-moving faces of the block and trough are of wear-resistant metal, and that it can be removed from the shuttle as a unit. C.

**Single-course Knitting Machine Conversion Means.** T. Booth. B.P.563,246 of 15/1/1943:4/8/1944. For beret or other knitting machines normally arranged to knit a single course of stitches at each operating stroke, conversion means are provided for knitting a number of courses at each operating stroke. In one embodiment, the means consist essentially of a cam track having a double reciprocating action for the needles and a double yarn guide carrying system with flexibly mounted yarn guides. C.

**Hair Nets: Production.** Byard Manufacturing Co. Ltd. and A. E. Hunter. B.P.563,497 of 19/11/1942:17/8/1944. A tube of openwork net fabric is produced on a twist lace machine and closed at intervals, there being provided a slit between successive closures, the slit being shorter than the distance between the closures, and the mouth of the slit being reinforced by a thicker thread, which is preferably extensible and may comprise a rubber thread or a knitted chain. After removal from the machine the tube is severed across the closed sections, each piece then forming a hair net of open-mouthed bag shape. C.

**Cop Winding Machine.** J. Mackie & Sons Ltd. and J. P. Mackie. B.P.563,549 of 12/4/1943:18/8/1944. In a cop winding machine of the type in which the spindle rotates, but does not move longitudinally, whilst the end of the cop is formed by a conical roller or rollers bearing on the tapered end, the cop being forced along the spindle as it is built up, the yarn is tensioned just as it passes to the nose of the cop by being bent sharply around a yarn tensioning bar disposed between the traversing device and the cop. The spindle is surrounded by a conical or tapering projecting surface just above the point where the nose of the cop being wound thereon will terminate, the projecting surface being such as to assist in preventing the yarn from creeping up over the spindle at the nose end of the cop. C.

**Winding Machine.** J. Mackie & Sons Ltd. and J. P. Mackie. B.P.563,613 of 10/5/1943:22/8/1944. A winding device for cross-winding rolls of yarn comprises the combination with a roller having one or two helical grooves in its surface without intersections for causing the yarn to be traversed either in one direction only, or from an intermediate point toward opposite ends of the roll to be wound, of a stationary yarn guide eye and a shaped breastplate or bar extending lengthwise of the grooved roller, and over which the yarn passes between such yarn guide eye and the grooved roller, the positions of the guide eye and breastplate or bar and the shape of the breastplate or bar being such as to control the whole return travel of the yarn from the leaving end of the groove back toward its starting point, or toward the entering end of an oppositely directed groove in the roller when two oppositely directed helical grooves are provided. The breastplate or bar may be formed with a surface such that over part of the return travel under the pull from the guide eye it retards the return of the yarn and over another part of the return travel it accelerates the return of the yarn, thus tending to make the return traverse of the yarn more uniform. C.

**Winding Machine.** J. Mackie & Sons Ltd. and J. P. Mackie. B.P.563,614 of 10/5/1943:22/8/1944. A winding device for cross-winding rolls of yarn comprises a guide eye for the yarn and a roller having outwardly directed helical grooves with overlapping inner starting ends for effecting the outward traverse of the yarn from an intermediate position, the grooves either having no return portions or short return ends only, the arrangement being such that the pull of the yarn from the guide eye serves to traverse the yarn back from the ends of the roller to the overlapping starting ends of the oppositely directed grooves,

whilst the guide eye is placed in front of the roller in a plane between the overlapping starting ends of the grooves. The pitch of the outwardly directed helical grooves may be varied so that it becomes less towards the outer ends of the traverse. For winding conical rolls the helical grooves are of unequal length, their overlapping ends being nearer to the larger end of the conical roll to be wound. C.

**Asbestos Yarn: Impregnating with Synthetic Resin.** American Cyanamid Co. B.P.563,678 of 30/4/1942:28/8/1944 (Conv. 30/4/1941). A method of increasing the mechanical strength of asbestos yarn comprises impregnating the yarn with a melamine-formaldehyde resin syrup, which can be cured under alkaline conditions, followed by curing of the resin. The resin syrup may contain suitable wetting agents and sizing and softening materials. C.

**Anti-static Yarn Lubricating Agent.** British Nylon Spinners Ltd., G. Loasby and D. L. C. Jackson. B.P.563,725 of 8/1/1943:28/8/1944. Threads, yarns, filaments, etc., which are liable to develop electrostatic charges during processing, e.g. cellulose acetate and nylon threads are treated with a lubricating composition comprising an aqueous solution or emulsion containing 2-10 per cent. by weight of a condensation product or products obtained by the interaction of 2-6 parts by weight of ethylene oxide with one part by weight of a higher fatty alcohol, and 2-10 per cent. of a lubricating oil. C.

**Silk: Softening.** A. F. Burgess (Institute of Paper Chemistry, U.S.A.). B.P. 563,745 of 29/6/1942:29/8/1944. Silk is softened by treatment in an oil emulsion adjusted to a pH preferably between 3.45 and 5.5. The treatment should be carried out at 70-100° F. for about 10-30 min. Preferably the silk is given a preliminary treatment in an acid rinsing bath. The softened silk, preferably after knitting, is subjected to a degumming treatment in a hot bath containing sufficient strong mineral acid and a buffer to maintain the pH at 1.0-2.9. The final finishing or dyeing step may be carried out in an acid medium. C.

**Twist Lace Machine.** Byard Manufacturing Co. Ltd. and A. E. Hunter. B.P.563,902 of 19/11/1942:5/9/1944. A twist lace machine is provided with means whereby across each of predetermined breadths of fabric the speed of take up is greater at the middle than at the sides. In one arrangement the usual porcupine roller is replaced by one or more cam shaped rollers the peripheries of which are displaced from the axis by a greater amount at the middle than at the sides. After passing over the rollers the work is wound on to one or more rollers as desired. In an alternative arrangement the porcupine roller and the cylindrical fabric-receiving roller are dispensed with and the fabric as made passes up the facing bar and is then received on a member mounted to rotate about its axis, the distance of the periphery from the axis being greater at the middle than at the sides. Shaped lengths of fabric or net of a predetermined breadth suitable for making into bag-shaped articles, such as hair nets, slumber caps, etc., can be produced. C.

**Winding Machine Traversing Element.** Abbott Machine Co. U.S.P. 2,338,085. The traversing element for movement adjacent to and lengthwise of a row of holders for winding packages comprises a tube to which yarns are directed from directions such that they bend round the tube in running on to the packages. C.

**Finned Stocking.** F. O. Donner (Chemnitz; vested in the U.S. Alien Property Custodian). U.S.P.2,338,375. A stocking is knitted with a fin-like strip projecting from the back of the leg, to serve as a reliable hold for the fingers of the wearer when pulling on the stocking. C.

**Flat Knitting Frame Yarn Moistening Device.** P. H. Aurich (Chemnitz; vested in the U.S. Alien Property Custodian). U.S.P.2,338,394. The yarn is run off from spools housed in horizontal casings disposed over water in a box, so that it can pick up moisture, there being openings in the top of the box and bottom of the casings. C.

**Flexible Winding Spool.** Industrial Rayon Corporation. U.S.P.2,338,513. The claim is for a tubular spool formed radially with dove-tailed grooves (four are shown) so that it is flexible under grip. C.

**Cord Pads or Mats: Production.** Dow Chemical Co. U.S.P.2,338,610. Cordage is wound on spools at such a ratio of traverse to winding speed that the layers cross at an angle between 15 and 60°, until the desired thickness has been reached. The wound package is then cut through from end to end of the spool and opened out to form a mat. C.

**Dobby Loom Shedding Mechanism.** Leopold Fuchs (North Bergen, N.J.). U.S.P.2,338,633. The claim is for an arrangement of griffe blades and bars and heald-actuating mechanism whereby the warp threads will not pass the centre of the shed at the same time as they are shifted from one line of the shed to the other by the reciprocating movement of the griffe blades. C.

**Webbing Loom Webbing Receptacle.** Thomas French & Sons Ltd., New York. U.S.P.2,338,638. The claim is for means to pass the webbing upwards in front of the loom to a receptacle above the loom. C.

#### 4—CHEMICAL AND FINISHING PROCESSES

##### (A)—PREPARATORY PROCESSES

**Hatter's Fur: Preparation for Felting.** Dyer, 1944, 92, 133-134. A short review of the literature dealing with the theory of carotting, and with mercurial poisoning, followed by a brief survey of recent carotting patents. W.

##### (B)—BOILING, SCOURING, DEGUMMING, AND WASHING

**Rayon Locknit Fabric: Scouring, Dyeing and Finishing.** Silk & Rayon, 1944, 18, 772-5; 992-4. Practical hints are given on economical methods of processing rayon locknit fabrics. C.

**Waste Kier Liquor: Utilisation.** C. C. Downie. *Textile Mercury & Argus*, 1944, 111, 250-253. A general note on the feasibility of recovering alkali from waste kier liquor by treatment in an absorption tower with flue gases. C.

##### (G)—BLEACHING

**Cellulose Hydrate Fibres: Washing and Bleaching.** G. Lietz. *Allg. Text. Z.*, 1943, 1, 48-52 (through *Chem. Zentr.*, 1943, ii, 1512 and *Chem. Abstr.*, 1944, 38, 3136<sup>5</sup>). Cellulose hydrate, its chemistry and structure, fibre-protective washing and fundamental washing operations (wetting of fibre, swelling of fibre and dispersion of the dirt in the bath) are discussed. The treatment should be faintly alkaline, with synthetic washing agents and without scouring. The bleaching agent should be used in the minimum amount necessary for formation of chloramines, or alkali and water should be used sparingly; any residual bleaching ingredients should be removed completely. The bleaching period should be as brief as possible. In the Ce-Es process, without kierung, the goods are impregnated with chlorine and bleached with hydrogen peroxide. C.

**Hypochlorite Solutions: Colorimetric pH Determination.** J. Jensen. *Skand. Tid. Textilind.*, 1942, 40, 71 (through *Chem. Zentr.*, 1942, ii, 1981 and *Chem. Abstr.*, 1944, 38, 3139<sup>5</sup>). Several commercial cellulose acetate films were treated with benzidine (0.5 g. per l. of water at 70°) and the colour reactions (depending on the pH) of alkaline hypochlorite solutions were determined. A small piece of the treated film was agitated for 2 min. below the surface of the solution and washed immediately with water. If the solution was nearly neutral and not too dilute, then the colour became reddish brown after 2 min. With increasing pH values the foil became brownish yellow and then assumed various shades of green; at pH values above 10 it became light blue. Increases in temperature or concentration changed the colour the same way as a decrease of alkalinity. Atmospheric carbon dioxide changed the colour of the water-treated foil. Prolonged exposure to the leaching solution had the same effect; however, in the latter case this change was slower, so that an accurate observation of the time was unnecessary. The blue colour is unstable and disappears when the film is stored for some time. Cotton was bleached with hypochlorite solutions of various concentrations and alkalinities and for various periods. Solutions that produced brown coloration with benzidine-treated films (pH 7.2-8.6) were the most harmful; those giving green coloration (pH 9-10) were effective and less harmful. Tables show the colours for different pH values and concentrations. C.

**Warps: Bleaching.** R. Golbs. *Klepzig's Textil-Z.*, 1942, 45, 613-614 (through *Chem. Zentr.*, 1942, ii, 2751 and *Chem. Abstr.*, 1944, 38, 3140<sup>2</sup>). Practical suggestions are made for bleaching according to the boiling, chlorinating and acid bleaching process, the Griesheim single-bath process, the combination bleaching method with hypochlorite and hydrogen peroxide, and the oxygen bleaching method. C.

#### (H)—MERCERISING

**Mercerisometer.** V. G. Parchomenko. *Tekstil. Prom.*, 1941, No. 4, 47 (through *Chem. Zentr.*, 1942, ii, 2220 and *Chem. Abstr.*, 1944, 38, 3140<sup>1</sup>). An apparatus is described by means of which can be determined (1) the degree of shrinkage of cotton yarn or of finished fabric, (2) the effect of concentrated alkali in the cold on yarn of short, medium and long fibre, and on fibre of different degrees of ripeness, and (3) the degree of shrinkage of yarns of different degrees of twist. C.

**Wool-like Cotton: Production.** A. Lagov. *Tekstil. Prom.*, 1941, No. 2, 49-51 (through *Chem. Zentr.*, 1942, ii, 2220-2221 and *Chem. Abstr.*, 1944, 38, 3138<sup>8</sup>). Mercerised cotton (8 kg.) was wetted with neutral "Kontakt" solution, treated with caustic soda, converted to cloth and then made into suits. The suits looked like woollen suits and after two years' wear were still in excellent condition. C.

#### (I)—DYEING

**N-Anthraquinonyl- $\beta$ -hydroxynaphthamide: Preparation and Use as Coupling Component.** E. Ferber. *Textilberichte*, 1942, 23, 580-600 (through *Chem. Abstr.*, 1944, 38, 3131<sup>7</sup>).  $\beta$ -Aminoanthraquinone (22 g.) and 18 g. of  $\beta$ -hydroxynaphthoic acid were ground fine with a little xylene, stirred into 300 c.c. of xylene, heated slowly to 60°, and 4.5 g. of phosphorus trichloride added. After 1 hour the temperature was raised to the boiling point. After 5-6 hours the evolution of hydrogen chloride stopped. The amide formed was purified with soda solution and hydrochloric acid; yield 81 per cent., m. 298° after crystallisation from nitrobenzene, soluble in pyridine, concentrated sulphuric acid and nitrobenzene and insoluble in water, benzene, toluene and glacial acetic acid. It can be converted to a vat dye readily by treatment with caustic soda and hyposulphite: the vat is dark red, is taken up readily by fibres, becomes dark brown after re-oxidation, and turns golden-yellow after acidification. It is absorbed much better than the usual Naphthol AS compounds and the dyes made by coupling are very fast to boiling. C.

**Orema Dyes: Properties and Application.** E. Krähenbühl. *Textilberichte*, 1943, 24, 315-316 (through *Chem. Abstr.*, 1944, 38, 3129<sup>9</sup>). These products of the Gesellschaft für Chemische Industrie in Basel are pigments of extremely fine state of division forming suspensions that are stable in water for several days. The suspensions are faintly opalescent. They can be fixed completely on the fibres to produce fast dyeings. The Orema printing inks consist of Orema dye, Orema fixing agent and Orema special thickening agent. The washing-fastness depends on temperature and length of heating period. The dyeing operation is described and various Orema products are tabulated. C.

**Delustred Rayons: Dyeing.** J. Lehembre. *Teintex*, 1942, 7, 192-194 (through *Chem. Zentr.*, 1942, ii, 2742-2743 and *Chem. Abstr.*, 1944, 38, 3132<sup>6</sup>). Substantive dyeing on delustred viscose and acetate rayons requires appreciably more dye than does dyeing on lustrous goods. The mat effect is suppressed greatly by dark, especially black dyeing. C.

**Rayolanda, Nylon, Casein and Alginate Textiles: Dyeing.** C. M. Whittaker. *Chemistry and Industry*, 1944, 269-271. A report of a lecture about the characteristics of the "new rayons" with special reference to their affinity for different classes of dye. C.

**Staple Fibre and Artificial Protein Fibre Fabrics: Dyeing.** G. Hammar. *Färgeritekn.*, 1942, 18, 173-178 (through *Chem. Zentr.*, 1943, i, 92 and *Chem. Abstr.*, 1944, 38, 3132<sup>3</sup>). A detailed discussion of the use of chromium-free dyes, the dyeing of strongly and slightly absorbing grades of staple fibre to the most nearly uniform colour tone possible, the dyeing of artificial protein fibres with preservation of the properties of the fibres, and possibilities of increasing wet resistance and lowering the sensitivity to higher temperatures. Numerous dyes which are suitable for the various purposes are mentioned. C.

**Cotton: Dyeing with Dye Mixtures.** J. Jensen. *Kem. Maanedstidende*, 1942, 23, 105-109 (through *Chem. Zentr.*, 1943, 1, 450 and *Chem. Abstr.*, 1944, 38, 3132<sup>7</sup>). The theory of dye adsorption by cellulose fabric and its application to dye mixtures (extension of Langmuir's equation) is discussed, and experiments are described on the dyeing of cotton with mixtures of a slowly dyeing dye with great affinity for cellulose (Chicago Blue B) and a rapidly dyeing dye of low affinity (Chrysophenin G). At all concentrations there was found a decrease in the amount of Chicago Blue adsorbed on the addition of Chrysophenin; however, the reverse was not the case. This is explained by the theory that after the entrance and adsorption of the quickly diffusing dye in the cellulose a displacement by the large molecules of the slowly diffusing dye becomes very difficult. C.

**Direct Dyeings: Improving Fastness to Washing.** I. T. Strukov and V. P. Smirnov. *J. Chem. Ind. (U.S.S.R.)*, 1941, 18, 12-16 (through *Chem. Zentr.*, 1943, 1, 331 and *Chem. Abstr.*, 1944, 38, 3133<sup>4</sup>). In order to improve the washing fastness of direct dyeings, condensation products of dicyanodiamide and formalin dissolved in acetic or formic acid are used. Solution in formic acid, however, causes some decomposition of the condensation product and lessens its ability to increase the fastness. The solution of the condensation product in the theoretical amount of acetic acid gave good results. The condensation product is not uniform; it consists of three substances which influence the various dyes to different extents. The solutions increased the washing fastness, but decreased the light fastness of the dyeings. The solution of the condensation products in acetic acid can be effected by introducing the acetic acid at the beginning of the condensation. Such a solution improves the washing fastness without influencing the light fastness. C.

**Sulphur Dyed Cotton: Adsorption of Other Types of Dyes.** V. V. Golosov and A. P. Smirenskiĭ. *Tekstil. Prom.*, 1943, 3, No. 10, 11-14 (through *Chem. Abstr.*, 1944, 38, 3133<sup>9</sup>). In wool fabrics containing cotton thread, the cotton is dyed with sulphur dyes, then the fabric is dyed by methods used for wool with acid or with chromium dyes. The double dyeing produces an uneven colour that is not fast to rubbing. This is attributed to adsorption of the acid dyes by the previously dyed cotton as well as by the wool. Bleached cotton fabrics were dyed first with sulphur dyes, then washed and dried, and treated with various acid, chromium and direct dyes. The results are tabulated and summarised. The adsorption of acid, chromium and direct dyes by cotton previously dyed with sulphur dyes is regarded as the formation of a lake on a colloidal substratum, since the sulphur dye, being amorphous, has a large adsorbing area. According to the electrochemical theory of dyeing, the hydrogen ions of the acid medium impart a positive charge to the sulphur dye on the cotton. This attracts the anions of the wool dye to the sulphur dye. The variations in the degree of adsorption of various dyes are explicable by the Goodall theory. Recommendations are made for reducing the adsorption of acid and chromium dyes by dyed cotton, for reducing the quantity of dye used and for avoiding defective dyeing. C.

**Microscopic Studies of Chemical and Physical Processes in Furs.** E. Lehmann. *Textilber.*, 1941, 22, 145-153 (through *Chem. Zentr.*, 1941, II, 410 and *Chem. Abs.*, 1944, 38, 1373). Furs present certain difficulties in cold dyeing operations, e.g. in a rabbit skin the wool-like hair is dyed well by an oxidation dye, while the straight hairs and guard hairs hardly absorb any dye. This problem was investigated by numerous microscopic studies of rabbit hairs. The structure of animal hairs requires that, for normal dyeing with oxidation dyes, (1) the epidermis membrane must retain its permeability, and the interaction between dichromate and hydrogen peroxide should not lead to spontaneous oxidations which fix the dye in the outer zone of the hair; (2) the size of the dye particles should be such that diffusion is possible; (3) the velocity of the dyeing process should correspond to the diffusion process. W.

#### (J)—PRINTING

**Indigosol Reserves: Development under Aniline Black.** W. Hess. *Textilberichte*, 1942, 23, 601-602 (through *Chem. Abstr.*, 1944, 38, 3131<sup>3</sup>). The disadvantages of the ammonium oxalate, the sodium citrate-aluminium chlorate, the dichromate and the sulphuric acid-nitrate processes are discussed. In oxidation by means of ferric salts, Prussian blue is deposited on the goods as a

result of reaction of the ferric salt with potassium ferrocyanide used as an oxygen carrier in the aniline-black bath. Laboratory tests showed that this can be removed by treatment with sodium carbonate and dissolving in acid the ferric hydroxide formed. However, this procedure is not very practicable on a commercial scale. Calgon can rapidly decompose Prussian blue to form sodium ferrocyanide and a soluble complex ferric metaphosphate. The following development process was worked out: The goods treated with aniline black were printed with white reserve and indigosol reserves, steamed 4-5 min. in a quick steamer, treated on a dyeing machine by means of a bath of 10 g. ferric chloride + 20 c.c. of 66° Bé. sulphuric acid per l. for 20 sec. at 90°, rinsed, treated in a hot bath of 3 g. sodium dichromate/l., and rinsed again, then soaped in a hot bath of 3 g. of Calgon + 3 g. of Gardinol/l. for 1-2 min. and washed. The sodium dichromate can be replaced with sodium percarbonate or potassium persulphate as this treatment is used merely to oxidise the aniline black completely. Large-scale tests showed also that Calgon can be replaced by Trilon A  $\{N(CH_2CO_2Na)_3\}$  or Trilon B  $\{C_6H_4[N(CH_2CO_2Na)_2]_2\}$ . The white and coloured reserves produced are very pure and bright. Some indigosol dyes, e.g. indigosol violet 1BBF, cannot be developed by this new process. Reserve printing with Rapidogen dyes and Indigosol dyes can be carried out readily. The development does not injure the colour tone of the Rapidogen print. C.

**Mordant Dyes: Fixation. Indigosols: Development.** E. Y. Podreshetnikov, N. E. Fedorova and A. N. Burlakova. *Tekstil. Prom.*, 1941, No. 5, 33-34 (through *Chem. Zentr.*, 1943, i, 331 and *Chem. Abstr.*, 1944, 38, 3131<sup>2</sup>). Steaming of ammonium chromate liberates chromium trioxide, which oxidises indigosols and is converted into chromium sesquioxide; ammonium chloride used simultaneously forms an acid medium. Based on these facts is a process for manufacture of a fast green dischargeable dye, which consists of indigosols and Chromcitronin. The process is described in detail. C.

**Vat Dye Prints: Steaming.** W. Hess. *Textilberichte*, 1942, 23, 346-348 (through *Chem. Abstr.*, 1944, 38, 3130<sup>3</sup>). The steaming operation is affected by physical and chemical factors. The conditions necessary for satisfactory steaming of textiles printed with vat dyes are discussed in detail. The use of sodium formaldehyde sulphonylate, caustic soda and potassium carbonate as textile assistants is described. C.

**Rayon Fabrics: Tendering in Printing.** *Ciba Review*, 1944, No. 47, 1715. In a particular style of printing, rayon fabric was dyed, printed with a discharge, and then, to avoid the formation of doctor streaks in ageing, padded on the printing machine with gum tragacanth and an assistant (Albatex BD). Tendering in the printed parts occasionally occurred and it was found that the fibre in these parts was completely flattened and more wettable. The explanation offered is that the yarns were sharply bent by the engraving of the printing roller, and were set in this bent condition by the drying of the printing paste. The pressure of the padding roller, combined with tension in the yarns due to irregular wetting, brought about rupture of the filaments. The trouble was cured by padding before printing. C.

**Steel Printing Cylinders: Copper-coating and Etching.** N. P. Batsyn. *Tekstil. Prom.*, 1943, 3, No. 10, 16-19 (through *Chem. Abstr.*, 1944, 38, 3134<sup>3</sup>). The preparation of copper-coated and engraved steel cylinders is described in detail. C.

**Viscose Rayon: Screen Printing with Acid Dyes.** R. Franzoso. *Textilberichte*, 1943, 24, 313-314 (through *Chem. Abstr.*, 1944, 38, 3134<sup>2</sup>). The operation is discussed in detail and suitable recipes are given. C.

#### (K)—FINISHING

**Natural and Artificial Fibre Mixture Fabrics: Resin Finishing.** T. S. McDuffey. *Textile Bull.*, 1944, 66, No. 2, 22, 24; No. 3, 10, 45-46 (through *Chem. Abstr.*, 1944, 38, 3138<sup>8</sup>). A discussion of the essential factors for obtaining well-prepared piece goods in the different blended constructions, and dyeing with direct cotton and acetate dyes and with vat dyes that are available for civilian use. Practical applications of melamine resins are discussed. C.

**Reducing Wool Shrinkage and Felting with Melamine Resins.** E. P. Johnstone. *Amer. Dyes. Rep.*, 1944, 33, 301-303. Methylol melamines, produced by the reaction of formaldehyde with melamines, are alkylated by alcohols,

e.g. methanol, to give resins which may be used to reduce the felting properties of wool (U.S.P. 2,329,622, these *Abs.*, 1944, A110). The wool is thoroughly impregnated at ordinary temperatures with a 2-15 per cent. solution of a water-soluble resin containing a suitable catalyst, the excess solution removed and the fabric dried. The resin, which is polymerised by heating at 230-300° F. for 4-45 min., is distributed uniformly throughout the fibres. The shrinkage-resistance of the fabric is not removed by repeated washing. W.

**U.S. Army Socks: Shrink-resistance.** Philadelphia Quartermaster Depôt, Research and Development Division. *Text. World*, 1944, 94, No. 5, 95. Part-wool socks are wet chlorinated in the grey, hypochlorites being used in conjunction with other retarding agents [unspecified] which produced a buffer effect. The life of the socks is increased 40 per cent. Specifications will be issued when problems have been solved involving choice of chemicals, prevention of over-treatment, and test methods. Similar treatment is being considered for 50 per cent. wool underwear. W.

#### (L)—PROOFING

**Aliphatic Chloromethyl Ethers: Preparation, Properties and Use in Finishing.** D. N. Kursanov and V. N. Setkina. *J. Appl. Chem.* (U.S.S.R.), 1943, 16, 36-46 (through *Chem. Abstr.*, 1944, 38, 3138<sup>9</sup>). In the course of the study of the interaction of compounds of the Velan type for water-repellent treatment of cellulose, the authors studied the preparation and properties of various chloromethyl ethers. The ethers were prepared by means of polyoxymethylene, hydrogen chloride gas and the corresponding alcohols. Properties of the butyl and higher ethers are indicated. The ethers are readily condensed with pyridine by mixing the reactants with cooling; the products, being poorly soluble in ether, are readily purified by washing with ether. They are soluble in water, the higher members forming opalescent solutions. The octadecyl ether was also condensed with trimethylamine in benzene solution, the product being insoluble in benzene and soluble in water. Dimethylaniline was used in a condensation with the tetradecyl ether; only 50 per cent yield of product was obtained even after 24 hours. Samples of cloth were treated with aqueous solutions of the ethers containing sodium acetate, dried, heated at 105° for 30 min., laundered and washed with benzene and water. Compounds of C<sub>11</sub> or higher alcohols imparted definite water repellency to cloth. Similar treatment in benzene-pyridine solution showed that compounds based on trimethylamine required a temperature of 140° for chemical binding to cellulose, the degree of water repellency being essentially unaffected by the nature of the nitrogenous base used. C.

**Canvas: Impregnation.** M. Chilikin. *Tekstil. Prom.*, 1943, 3, No. 11/12, 13-15 (through *Chem. Abstr.*, 1944, 38, 3141<sup>9</sup>). For impregnating canvas, paraffin may be replaced by ceresin and ozocerite, and soap can be replaced by naphthenates obtained as by-product from oil distilleries. The use of iron salts does away with the need for acetic acid, substituting for it basic aluminium sulphate. Wastes, e.g. from dichromate manufacture, contain up to 28 per cent. of aluminium oxide soluble in sulphuric acid. This should be salvaged and used in canvas plants. Alunite deposits in central Asia are another source of aluminium sulphate. Oak extracts can be successfully replaced by extracts of willow, pomegranate, Mongolian tea, etc. These are used for fixing copper and chromium salts. C.

**Furs: Mothproofing.** D. Traill, A. McLean and H. H. S. Bovingdon. *Chem. & Ind.*, 1944, 284-286. A description of the experimental work which led to the development of mothproofing furs with a saturated solution of sodium chloride containing small concentrations of formaldehyde and hydrochloric acid. The process is covered by B.P. 548,061 (these *Abs.*, 1943, A26). Using this treatment, the results are given of mothproofing tests on furs under different conditions of pH, time and temperature, and on furs dyed after proofing. For furs, the treatment should be comparatively inexpensive, and would replace the usual acid/salt pickle. In oviposition tests on wool, the number of eggs laid on the untreated material was over 10 times as great as the number laid on treated material, but the economic use of the treatment would appear to be doubtful. W.

## PATENTS

**Water-sensitive Rayon Fabrics: Production.** J. G. Williams and L. Krause. B.P.563,133 of 7/12/1942:1/8/1944. Textile materials having a very low wet strength but a substantial dry strength are produced by subjecting an organic ester of cellulose, particularly the acetate, in the form of filaments or yarns, but preferably as fabric, to the hydrolytic action of dilute sulphuric or hydrochloric acid, until the wet strength of the material has been reduced to the desired value. C.

**Stable Hypochlorite Solutions: Preparation.** W. R. Bruce. B.P.563,136 of 21/2/1943:1/8/1944. Stable sodium hypochlorite solutions are prepared by adding calcium hypochlorite to a hot aqueous solution containing considerable excess of alkali carbonate over that required to convert all the calcium to calcium carbonate and separating the latter from the dissolved alkali hypochlorite. The addition of sodium chloride either simultaneously with or subsequently to the addition of the calcium hypochlorite is advisable. The alkali carbonate may be employed partly or wholly as bicarbonate and the solution may also contain borax and/or magnesium carbonate. C.

**Cellulosic Textile Materials: Finishing.** American Cyanamid Co. B.P. 563,172 of 15/8/1942:2/8/1944 (Conv. 30/8/1941). A method of finishing cellulosic textile materials, comprises applying an aqueous solution of a methylated methylol-melamine, and then curing the agent to a substantially water-insoluble condition. Fabrics may be filled and weighted and given a soft, springy handle and a fair degree of water repellency by such treatments. Substantial resistance to shrinking is imparted by the application of 2-8 per cent. by weight of the agent. With 8-14 per cent. the fabrics acquire increased resistance to shrinkage and also crease-resisting properties. The treated materials show unexpectedly low chlorine retention when subjected to laundering operations involving bleaching steps. C.

**Cellulose Acetate Materials: Dyeing.** British Celanese Ltd. B.P.563,181 of 5/11/1942:2/8/1944 (Conv. 12/11/1941). Cellulose acetate is subjected to the action of 23-40 per cent. caustic alkali at such a temperature and for such a time that the percentage of acetyl (calculated as acetic acid) is not reduced by more than 7, washed, and dyed with a direct dye. The caustic alkali treatment increases the affinity of the material for the dye and the resistance to acid fading of the resulting colouration is notably better than that produced without the alkali treatment. In general good results are obtained by alkali treatments at 20°-30° C. for periods of 30-120 sec. The method described is particularly advantageous for the dyeing of fabrics woven from yarns which are normally dyed to deep shades only with difficulty, i.e. yarns of high denier having a high filament count. C.

**Light-resistant Cellulose Derivative Compositions.** H. Dreyfus. B.P. 563,287 of 6/11/1942:8/8/1944. The undesirable action of ultra-violet light on fibres, foils, and similar products having a basis of cellulose acetate or other cellulose ester or ether can be greatly reduced by including in the composition up to 15 per cent. of an ester of low volatility of a hydroxybenzene or hydroxynaphthalene monocarboxylic acid, with a phenol, an alcohol containing an aromatic nucleus, or a cyclo-aliphatic alcohol. This ester may be added to spinning solutions or the formed products may be impregnated with solutions of the ester. A film (0.002 in. thick) of cellulose acetate containing about 5 per cent. of  $\beta$ -naphthyl salicylate on the weight of the cellulose acetate suffers, on exposure to light from a mercury vapour lamp, a percentage loss in strength of only about one-eighth of that of a similar film free from the salicylate. The esters are substantially retained in the material and remain effective during normal storage and use of the cellulose ester or ether products. C.

**Waterproof Fabric: Production.** Lustrafil Ltd. and G. L. Godman. B.P. 563,586 of 9/10/1942:22/8/1944. A process for the manufacture of waterproof fabric by impregnating and/or coating a cellulosic fabric with a resin and then with a non-tacky varnish is characterised by the feature that the first resin is an adhesive oil-modified alkyd resin substantially free from protein or any other synthetic resin, so as to produce a pliable fabric capable of high resistance to repeated stretching and bending. The outer or final coating is an oil, lacquer or varnish such as is normally employed in the production

of oiled fabrics or is capable of being so applied. When more than two coatings are applied the intermediate coating or coatings may consist of a mixture of a varnish with the synthetic resin forming the first coating or plasticizing agents or both. Fabrics may be coated on one or both sides. The fabrics may be dyed or printed or treated with softening agents or rendered crease-resistant prior to coating and pigments or soluble dyes may be incorporated in the film-forming solutions or dispersions applied. The waterproof fabrics produced by this method may be used for the production of waterproof garments, transparent curtains and decorative materials. C.

**Polyvinyl Adhesive Compositions.** British Thomson-Houston Co. Ltd. B.P. 563,624 of 7/10/1942:23/8/1944 (Conv. 10/10/1941). An adhesive composition comprises a solvent and a resinous component which consists of 10-50 per cent. of a polyvinyl ester, e.g. polyvinyl acetate, and 50-90 per cent. of a resinous mixture consisting of the reaction product of endomethylene tetrahydrophthalic anhydride and polyhydric alcohols averaging 2-3 hydroxyl groups per molecule and the reaction product of maleic anhydride and polyhydric alcohols averaging 3-4 hydroxyl groups per molecule, the endomethylene tetrahydrophthalic anhydride reaction product being present in a major amount and the maleic anhydride-polyhydric alcohols being present to the extent of at least 5 per cent. Compositions of this type may be used for bonding steel laminations and the individual turns of electric coils, in the manufacture of laminated glass fibre and asbestos articles, and for the bonding of mica to a backing of glass fibre cloth. C.

**Dyeing Tank or Vat.** Mellor Bromley & Co. Ltd., S. R. T. Freeman and G. S. Helliwell. B.P. 563,634 of 23/11/1942:23/8/1944. A tank or vat for treating materials with dyeing and other liquids is constructed with a bottom of uniformly rounded form and with a perforated tube or tunnel in the rounded formation at or near the bottom which provides for the circulation of the liquid and accommodates a propeller or propellers whereby the liquid is circulated. Preferably, the upper part is flared and the tank or vat is suspended from supporting members, e.g. parallel beams or bars, without enclosure in a casing. The described construction and mounting minimise buckling, facilitate cleaning, and reduce matting of hanks. C.

**Fabric Shrinking Apparatus.** J. J. Hadfield and D. Bamford. B.P. 563,638 of 18/2/1943:23/8/1944. Apparatus for shrinking fabrics comprises an endless and elastic rubber band adapted to be supported upon and driven by revolvable rollers, wherein one of the rollers is driven through variable speed mechanism at a variable higher speed than the preceding roller so that a portion or section of the endless band is in a state of tension or stretch proportional to the relative speeds of the rollers when it receives the wetted or conditioned fabric, which tension or stretch is relaxed with a resulting contraction in length equal to the amount of stretch over each successive length of the endless band where it makes contact with the intervening fabric against a revolving burnished drying cylinder the location of which causes successive lengths of the resiling endless elastic band and fabric to follow the contour of the highly burnished cylinder while shrinkage of the fabric takes place, the extent of the shrinkage of the fabric being proportional to the contraction of each successive length of the endless band. C.

**Resin Dispersions: Preparation and Application.** E. I. Du Pont de Nemours & Co. B.P. 563,707/8/9/10/11/12/13 of 5/8/1941:28/8/1944 (Conv. 3/8/1940). (1) Stable dispersions of polymerised methacrylic acid esters which are useful for the treatment of textiles and are compatible with many finishing agents are produced by agitating a monomeric methacrylic acid ester containing a small proportion of a polymerisation catalyst, e.g. benzoyl peroxide, with so much of an aqueous solution of a partially saponified polyvinyl acetate having a saponification number between 40 and 130 and in a 4 per cent. (by weight) aqueous solution a viscosity between 10 and 30 centipoises at 20° C., as will give between 0.75 per cent. and 5 per cent. by weight of partially saponified polyvinyl acetate in the dispersion until a dispersion of the monomer is obtained and then heating to produce polymerisation of the methacrylic acid ester. (2) Stable dispersions which are substantive to animal and nylon fibres are prepared as described above, but with the addition of a water-soluble salt of a heavy metal or a multivalent metal. (3) Dispersions which are substantive

to nylon, animal and cellulose fibres are prepared as in (1) but with the addition of a cationic surface tension reducing agent and, if desired, a water-soluble salt of a heavy metal or a multivalent metal. (4) Stable resin dispersions suitable for the treatment of textile materials are produced by dissolving a natural or synthetic resin in a methacrylic acid ester, adding the solution to an aqueous solution of a partially saponified polyvinyl acetate of the characteristics and in the proportion specified in (1), agitating the mixture until a dispersion is obtained and thereafter heating to cause the methacrylic acid ester to polymerise. (5) Stable resin dispersions which are substantive to animal and nylon fibres are prepared by dissolving a resin in a methacrylic acid ester, adding a solution of partially saponified polyvinyl acetate as above, and agitating the mixture in the presence of a water-soluble salt of a heavy metal or a multi-valent metal. (6) For the production of dispersions which are substantive to nylon, animal and vegetable fibres, the mixture of (4) is agitated in the presence of a cationic surface tension reducing agent and, if desired, of a water-soluble salt of a heavy metal or multivalent metal. (7) A resin dispersion which is substantive to nylon, animal and cellulose fibres comprises an aqueous dispersion of a polymer of a methacrylic acid ester which has been polymerised in the presence of an aqueous solution of a cationic surface tension reducing agent and, if desired, of a water-soluble salt of a heavy or multivalent metal. A natural or synthetic resin may be dissolved in the methacrylic ester. Examples are given of the application of these resin solutions in the finishing of textile materials. C.

**Mordant Monoazo Dye: Production.** Brotherton & Co. Ltd. and P. C. Holmes. B.P.563,772 of 22/2/1943:29/8/1944. A mordant monoazo dye is produced by coupling *m*-xylenol with diazotised picramic acid. It gives an olive green tone when dyed on wool by the after-chrome or single bath chroming processes. C.

**Fabrics: Joining by Fusion.** British Celanese Ltd. (Celanese Corporation of America). B.P.563,860 of 13/1/1943:1/9/1944. A method of joining edge to edge pieces of textile fabric, at least one of which consists of or contains thermoplastic material, comprises bringing together surfaces of marginal portions of the fabric adjacent to the edges and at a series of spaced positions within the area of contact, heating the fabrics so as to render the thermoplastic material adhesive and attach one of the pieces of fabric to the other at the said positions. With non-thermoplastic fabrics, the marginal portions of the fabrics are brought together with an interposed strip of thermoplastic foil, film or textile fabric, and the assembly is heated at spaced positions. A device suitable for carrying out the joining operation comprises a handle, a roller mounted on the handle, a number of elements capable of being heated and carried by the roller, at least a part of these elements projecting from the periphery of the roller, and means for applying heat to the elements. The elements carried by the roller may consist of projections such as ribs, teeth or bars which can be heated and which, when brought into contact in the heated condition with the pieces of fabric to be joined together, will effect localised heating in a pattern defined in accordance with the disposition of the projections. C.

**Tentering Machine Vacuum Extractor.** Celanese Corporation of America. U.S.P.2,338,167. The cloth passes over a slotted vacuum tube for sucking off liquid. A tape, responsive to the movement of the tenter table, is attached to one end of the tube to close a portion of the slot. C.

**Laminated Elastic Fabric: Production.** United States Rubber Co. U.S.P. 2,338,243. Elastic rubber sheet is bonded to a fabric that is more condensed and extensible in some areas than in others. C.

**Pigment Fabric Decorating Composition.** Interchemical Corporation. U.S.P. 2,338,252. A pigment is dispersed in a mixture of polyvinyl alcohol solution and urea-formaldehyde resin to which is added a nitrogenous base that will evaporate from a thin film of the composition in a few minutes at 150° C. The base prevents the mixture from gelation in storage. C.

**Tubular Knitted Fabric: Finishing to Simulate Woven Fabric.** L. te Strake (Netherlands; vested in the U.S. Alien Property Custodian). U.S.P.2,338,386. Tubular knitted fabric is fulled in a soap solution at 25° C. for 1-2 hours, then

joined end to end and passed continuously through the soap for another 1-2 hours, so that it shrinks 40-50 per cent. in length and 25 per cent. in width, and finally dried under tension so that the circumference increases again by about 10 per cent. C.

**Fabric Containing Thermoplastic Fibre: Shrink Finishing.** American Viscose Corporation. U.S.P.2,338,391. Fabric containing thermoplastic fibre is advanced under stretch and treated with a swelling agent so as to increase the crimp in the weft, then heated to make the thermoplastic fibre tacky, allowed to shrink under compression, and finally cooled and set. C.

**Beaded Upholstery Fabric: Production.** National Automotive Fibres, Inc. U.S.P.2,338,490. A flat piece of uncured, blowing rubber stock is laid on a panel board, covered with a fabric, and then put under a deeply recessed die to which suction can be applied to draw the fabric and rubber into a raised bead. Heat is then applied to vulcanize the rubber and cause it to blow and fill the bead. C.

**Cellulose Esters: Rendering Susceptible to Basic Compounds.** Eastman Kodak Co. U.S.P.2,338,587. Partially hydrolysed lower fatty acid esters of cellulose are rendered susceptible to basic compounds by treatment with 1-2 molecular proportions of nitrogen dioxide and 1-10 per cent. of moisture. C.

## 5—ANALYSIS, TESTING, GRADING AND DEFECTS

### (A)—FIBRES

**Cambodia Cotton Fibres: Measurable Characters; Variations with Place of Growth.** R. L. N. Iyengar. *Indian J. Agric. Sci.*, 1943, 13, 434-445. A report is given of observations of the variations in the measurable characters of the same set of cottons grown at two different places (Coimbatore and Srivilliputhur) for five seasons. The material was collected from pure strains of Cambodia cotton (*G. hirsutum*). Seed weight, lint weight, ginning percentage, mean fibre length, mean fibre weight per cm., unit fibre weight, standard fibre weight, number of fibres per seed and maturity percentage were determined, and the mode of development of the fibres was studied. The results show that at Srivilliputhur the fibres are longer, finer, more mature, but fewer in number on the seed than at Coimbatore. The maturation period of the boll and the lengthening and thickening phases of the fibre are less and hence the rate of length development and the rate of secondary wall deposit are higher at Srivilliputhur. The improved length and fineness of the fibres and the reduction in their numbers per seed at Srivilliputhur appear to be caused by the higher temperature and solar radiation at this place. C.

**Cotton Fibre Primary Wall: Structure.** K. Hess, W. Wergin and H. Kiessig. *Planta*, 1942, 33, 151-160 (through *Chem. Zentr.*, 1942, ii, 2220). Based upon information gained from the study of young seed hairs the authors propose a model for the structure of the primary wall of which the characteristic feature is the concept of ribs of cellulose-pectin. These ribs are diagonal to the axis of the hair and are encased in a sheath of fat and wax. The attachment of the sheath to the rib is supposed to involve lecithin. The primary wall can consist of no more than a single lamella. C.

**Damaged Fibre: Testing.** H. Rath and W. Meyer. *Textilberichte*, 1943, 24, 353-355 (through *Chem. Abstr.*, 1944, 38, 2826<sup>a</sup>). The mechanical testing of fibre deterioration brought about by chemical or thermal action is useful only when this deterioration is rather extensive as measured by changes in the degree of polymerisation. On the other hand, in some cases mechanical tests indicate changes in the fibre that cannot be measured fully by determination of the degree of polymerisation. For changes that cause embrittlement, and hence a decrease in the elasticity of the fibre, measurement of elasticity is a better criterion than is measurement of strength. Extensive bleaching damages can be detected not only by the decrease in the degree of polymerisation but also by the decrease in tensile strength on boiling the bleached goods with sodium carbonate. Measurement of the degree of polymerisation is not applicable to the determination of fibre deterioration of staple fibre that has been pretreated with strong caustic soda solution; mechanical tests are necessary. C.

**Fibres: X-ray Analysis.** Institute of Physics. *J. Sci. Instruments*, 1944, 21, 115-117. An illustrated report of a conference, with summaries of contributions by (1) W. T. Astbury, calling attention to the failure of X-ray photography to distinguish between normal, acid-tendered and oxidised cotton; (2) E. Aruja, on peculiarities in the structure of chrysotile (asbestos); and (3) C. W. Bunn, on the structure of simple high-polymers, like polyisobutylene filaments, which show very many sharp spots in the stretched condition. C.

**Textile Fibres: Molecular Orientation and Physical Properties.** J. W. Illingworth. *Textile Recorder*, 1943, 61, September, 44-48; 1944, 61, February, 56-61. A broad review of recent work on the influence of molecular orientation on (a) strength, (b) extensibility, (c) swelling, (d) crease resistance, (e) dye affinity, (f) lustre. C.

**Cotton, Silk and Wool: Density and Sorptive Capacity.** P. M. Heertjes. *Rec. trav. chim.*, 1942, 61, 751-762 (through *Chem. Zentr.*, 1943, i, 228-229 and *Chem. Abstr.*, 1944, 38, 3137<sup>n</sup>). The density of a hydrophilic fibre in water is considered theoretically. The true volume of water held by 1 c.c. of dry fibre is  $1 + (q^1/100) = d_h[(p/s) + (1/d_w) + (1/d_h) - (1/d_b)]$ , where  $q^1$  = volume increase by water taken up minus the volume of the non-accessible pores of the fibre as determined by sorption with benzene  $d_h$ ,  $d_w$ ,  $d_b$  = the densities of the fibre in helium, water and benzene,  $s$  = density of water and  $p$  = g. of water adsorbed per g. of fibre substance. At first the water molecules enter the outer layers of the fibre. Then the water intake continues by adsorption on the inner and outer fibre substance without any noticeable change in volume. Finally the water is taken up by capillary condensation in the pores of the fibre, still without any noticeable change in volume. The absorbed water affects the determination of the density of the fibre in water, but not the adsorbed water and water taken up by capillary condensation. For cotton and silk, dyed and undyed fibres take up the same quantities of water. The affinity of wool for water is increased appreciably by dyeing and felting. C.

**Cotton, Wool, and Dyes: Effect of High Temperatures.** H. J. Henk. *Spinner u. Weber*, 1942, 60, No. 11, 22-23 (through *Chem. Zentr.*, 1943, ii, 1685 and *Chem. Abstr.*, 1944, 38, 3132<sup>n</sup>). Cotton withstands temperatures up to 300° for short periods, but chars completely at 120° after several months. At 80° there is a decrease in elasticity and dye absorption; at 180° the elasticity has dropped 50 per cent. and the dye absorption becomes nearly zero. Water absorption and fluorescence change similarly with heating. Wool is damaged by brief heating to 150° and by prolonged heating to 50°. Substantive dyes are decomposed completely at 270°; Naphthol AS dyes, only above 300°. Superheating on driers should be avoided, particularly with fabrics that have been impregnated with chlorides or sulphates. C.

**Degummed Silk: Moistening.** S. Avirom. *Legkaya Prom.*, 1940, 19, No. 11-12, 39-44 (through *Chem. Zentr.*, 1941, ii, 3014-3015 and *Chem. Abstr.*, 1944, 38, 3138<sup>n</sup>). Results of laboratory tests showed that (1) the higher the relative humidity in the moistening chambers the faster the moisture absorption by silk and (2) the humidity in these chambers should be held at 92-98 per cent. in order to prevent condensation of water on the fibre. The correctness of the laboratory tests was checked by plant tests at 92 per cent. relative humidity at 18-20°. On an industrial scale the new method showed many advantages, increased the yield of carded fibres and improved the quality of the goods. C.

**Fibres: Determination in Mixtures.** G. Romeo. *Laniera*, 1942, 56, 179-199 (through *Chem. Zentr.*, 1943, i, 583 and *Chem. Abstr.*, 1944, 38, 3136<sup>n</sup>). The table includes wool, silk, cotton, hemp, jute, lanital, rayon and acetate rayon. The fibres are identified by macroscopic and microscopic examination and by the use of the following reagents: acetone, 58° Bé. sulphuric acid, basic zinc chloride solution ( $d. 1.835$ ), 10 per cent. caustic soda, Löwe's copper solution containing glycerol, 20 per cent. sodium sulphide solution, 8 per cent. sodium sulphide solution and ammoniacal copper oxide solution. Formulæ are given for calculating the proportions and numerous tables are shown. C.

**Fibres: Fine Structure and Properties.** K. Hess. *Textilberichte*, 1943, 24, 287-293 (through *Chem. Abstr.*, 1944, 38, 3135<sup>n</sup>). A discussion of molecular

size, structure and fibre properties, strength of synthetic fibres and comparison with natural fibres, the natural formation of the cotton hair and optical-microscopic and electron-microscopic examination of natural cellulose fibres. C.

**Iodine Fibre Stains: Activity.** H. W. Rowe. *Paper Trade J.*, 1943, 116, TAPPI, 102-110. Literature on the mechanism of fibre staining by agents containing iodine is reviewed from the time of Gmelin (1830). Typical iodine stains for paper-making materials are described and their staining effects on acetylated cotton celluloses (Ac. 8.7, 57 and 61 per cent.) are tabulated. Accounts are also given of the staining of various celluloses from spruce and oxycellulose, of the effects of pre-treatment of fibres with salts before staining, and of the effects of adding salts to the staining reagent. The effects are interpreted in terms of colloids. C.

**Photo-electric Photometer: Construction and Applications.** N. H. Chamberlain. *J. Textile Inst.*, 1944, 35, T61-76. C.

**Pulp Fibres: Ultimate Strength.** J. d'A. Clark. *Paper Trade J.*, 1944, 118, TAPPI, 1-6. The author reviews attempts to utilise the breaking load of a pulp test sheet between close jaws ("zero span") as a measure of the ultimate fibre strength and therefore of the tendering effects of bleaching and similar agents. An improved type of jaw is described that ensures fit of the edges to within 0.0001 inch. Experimental data are recorded in demonstration of the following effects: (1) Clamping pressure, with sheet cellulose and a soft, bulky paper; (2) Extent of beating of the pulp; (3) Fibre length, long fibres being collected separately on a 20-mesh screen; (4) Addition of locust bean mucilage to the pulp. It is shown that the "zero span" breaking loads are influenced to an extremely small extent by the compactness of the test sheet and by the bonding that results from beating or adding mucilage, but they are rather more dependent on fibre length. The test is not, therefore, a fundamental measure of ultimate fibre strength, but appears to offer a fairly good indirect measurement of that property. It is preferred to the more laborious determination of bursting strength on pulp sheets. C.

**Sea Island Cotton: Mildewing.** D. E. Klemme. *J. Bacteriology*, 1942, 43, 171-180 (through *Exp. Sta. Rec.*, 1943, 88, 424). Sea Island cotton fibre and yarn were sterilised and inoculated with a strain of *Chaetomium globosum*, isolated from mildewed canvas, and incubated for 28 days in a Warburg apparatus of the seven-manometer, refrigerated type. The growth of the organism was followed by daily measurements of oxygen consumption and by determination of catalase production as measured by the amount of hydrogen peroxide decomposed. In general the rate of growth of the organism on the fibre and on the yarn increased during the first 11 days, as indicated by the increased daily rate of oxygen consumption, after which it decreased. The amount of oxygen absorbed by the fungus growing on the fibre was significantly greater than that absorbed by the fungus growing on the yarn. Likewise, the amount of catalase produced by the fungus on the fibre was greater than on the yarn. These results indicated that, in general, raw cotton would deteriorate more readily in a moist atmosphere than would yarn or fabric, and more care, therefore, should be taken in storing the fibre. The accumulated amount of oxygen absorbed by the organism was estimated by adding the amount absorbed each day to the amount absorbed on previous days. The total amount absorbed by the fungus growing on 1 g. of the fibre for 28 days was 0.32 milliequivalent and on 1 g. of yarn 0.21 milliequivalent. By the method of least squares a fourth degree polynomial equation was found for the accumulated absorption values for the fibre and another for the yarn. C.

**Wool: Combination with Acids.** G. A. Gilbert and E. K. Rideal. *Proc. Roy. Soc.*, 1944, A 182, 335-346. An approximate titration equation is developed for the reaction between fibrous proteins and acids (wool; hydrochloric and sulphuric acids) in which account is taken of the valency and intrinsic affinities of the acid anions, and of the limited number of adsorption sites available for anions. The transition from soluble to fibrous proteins is traced in order to demonstrate that the main difference between their titration

curves arises from the difference in potential developed during the adsorption of protons. C.

**Keratin Fibres: Elasticity.** H. B. Bull and M. Gutmann. *J. Amer. Chem. Soc.*, 1944, 66, 1253-1259. The stress-strain relations of human hair have been investigated. It is concluded that irreparable damage to the hair occurs at extensions greater than 18 per cent.; below this extension the process is reproducible but essentially irreversible. It is suggested that Astbury and Bell's newer structure of  $\alpha$ -keratin (these *Abs.*, 1941, A385) is still too condensed, and that a process resembling a thixotropic gel-sol transformation occurs when hair is extended 3-20 per cent. W.

**Wool Fineness: Measurement.** H. J. Wollner, L. Tanner and H. H. Spiegel. *Amer. Dyes. Rep.*, 1944, 33, 307-308, 321-322. Von Bergen's wedge method for measuring fibre width (these *Abs.*, 1933, A60) has been modified, and the speed and precision of the measurements greatly increased. The modifications cover (1) the preparation of the slide for the projection of longitudinal fibre images, and (2) an improved measuring device. (1) The fibres are cut to very short lengths, about 75 microns, from sections prepared by the technique of Hardy and others (these *Abs.*, 1935, A316 and 1936, A335). A well-prepared slide shows a compact single layer of short fibres from which many measurements can be made after a single adjustment of the focus and stage. (2) A measuring device which retains the advantages of the wedge ruler and overcomes its disadvantages is illustrated. It consists of a calibrated spiral of Archimedes on a transparent rotary circular plate mounted on a baseboard. The latter serves as a screen for the image and is provided with four radial index lines with base lines normal thereto. Radii divide the curve into serially numbered sectors of uniform angular opening. Since the distance along an index line between a base line and the curve depends on the angular displacement, each section is a "cell" covering a fixed range of lengths. The fibre image is projected through the transparent scale on to the base. The device is moved so that a base line is tangent to one side of the superposed image at the desired point as defined by the index line. The scale is then rotated until the curve meets the intersection of the opposite side of the image with the index line, and a mark made with a soft crayon on the transparent scale in the cell over the index line. The process is repeated on other images until the required number of fibres has been measured. The number of marks in each cell is counted and the necessary calculations made. These are shown in tabular form and are based on the official method of the U.S. Dept. of Agric. (Amendment No. 2 to Service and Regulatory Announcement 135) and the Amer. Soc. for Testing Materials (these *Abs.*, 1942, A142). W.

## (B)—YARNS

**Nylon Yarn: Properties.** E. I. Du Pont de Nemours & Co. *Textile Manufacturer*, 1944, 70, 355-357; *Rayon Textile Monthly*, 1944, 25, 169-171. An authoritative statement, with data, concerning the breaking load and elongation, resistance to chemicals, resistance to abrasion, density, elastic recovery, delayed recovery, modulus of elasticity, inflammability, specific heat, heat of fusion, resistance to heat, resistance to insects and micro-organisms, resistance to light, moisture regain, shrinkage and swelling, and content of material lost in scouring, of recent nylon yarns. C.

**Yarn Twist Factor Formula: Extension to New Materials.** S. L. Gerhard. *J. Applied Physics*, 1944, 15, 474-476. Various yarn properties are defined and discussed and a brief explanation is given of the derivation of the conventional twist formula  $T = M\sqrt{C}$ , where  $T$  is the twist in turns per inch,  $C$  the yarn count and  $M$  the twist factor. Extensions are developed by means of which it is possible to copy a yarn made of familiar material in a new material and obtain the same helix angle, and to determine approximately the twist that should be inserted in spinning a new yarn and thus shorten the trial and error procedure necessary for finding the optimum twist. The calculation involves the filament density and the following values, in lb. per cubic foot, are tabulated: Paper 44-72, silk 78-81, wool 82-83, acetate rayon 83, cotton and linen 94-95, viscose rayon 95, cuprammonium rayon 95-96, nitro rayon 95-97, rubber 56-69, asbestos 156-165, glass 150-175. A simple formula is also derived for converting twist factors from one yarn count system to another. C.

## (C)—FABRICS

**Hosiery Shrinkage Measuring Device.** Textile Section, U.S. National Bureau of Standards. *Textile Research*, 1944, 14, 150-151. A device for measuring the dimensions of the feet of socks and other hosiery under different loads and the shrinkage produced by laundering consists essentially of a flat metal form made in two parts and having the shape of a boarded sock. One part includes the region of the toe and has a flat extension the full width of the foot which slips between the faces of the second part of the form. Thus it is possible to draw out the foot of the form to fill socks of different sizes, the width of the foot of flattened socks being the same for different sizes. The second part of the form, which includes the rest of the foot, heel and ankle, is provided with means for attaching it to the pulling member of a tensile testing machine and with a clamp for holding a sock on the form. In carrying out a test the sock is placed on the form and clamped at a fixed position across the ankle. Another clamp is attached to the toe by means of a pin which passes through the sock and through a hole in the form near the toe. This clamp is attached to the weighing mechanism of the testing machine. The length of the sock at different loads without reduction in width is obtained from the stress-strain record of the machine. By testing socks before and after laundering, changes in dimensions at stated loads may be evaluated. Similarly, socks may be loaded and unloaded repeatedly, and the accompanying changes in dimensions at stated loads may be measured. The device may be used without the tensile testing machine by attaching one end to a rigid support and adding weights to the other while it is hanging freely, and measuring the length of the sock on it. C.

**Cotton Goods: Testing.** F. H. Thies. *Kleppig's Textil-Z.*, 1942, 45, 434-439 (through *Chem. Zentr.*, 1942, ii, 2961 and *Chem. Abstr.*, 1944, 38, 3138<sup>6</sup>). Methods suitable for the industrial laboratory for determination of strength, determination of carbon and nitrogen, testing for oxycellulose, and investigation of the course of industrial processes are discussed. C.

**Substantive Dyed Cotton Fabric: Effect of Light and Weather on Strength.** F. I. Sadv and N. Kreindlina. *Tekstil. Prom.*, 1943, 3, No. 7/8, 11-14 (through *Chem. Abstr.*, 1944, 38, 3133<sup>6</sup>). Cotton fabric dyed with substantive dyes by various procedures, and fabric bleached but undyed, were exposed to weather facing south at a 45° angle for 3 months. Both dyed and undyed samples decreased in strength; this weakening was no greater in the dyed samples, and was even less than in the undyed if the dyed contained sufficient amino and hydroxy groups. Making the dye fast to washing by diazotisation followed by coupling with naphthols lowers the strength and light fastness of the fabric appreciably. Making the dye fast to washing by treating it with a dicyanodiamide condensate and fast to light by treating it with a copper salt increases the light resistance of the cotton considerably. The light fastness of some of these dyes compares favourably with the light fastness of indanthrenes; the indanthrenes contribute to the disintegration of the cotton fabric. C.

**Fabrics and Yarns: Resistance to Insect Pests.** J. R. Bonnar. *Amer. Dyes. Rep.*, 1944, 33, P266-269. Nine different fabrics, patterns of each being moth-proofed by different types of treatments, were tested in 12 different laboratories for resistance to moth attack, using both the excrement weight method and the fabric loss method. Comparison of the results showed that agreement was found from laboratory to laboratory only on the report of visual damage. The other results, although not varying greatly within each laboratory, varied too much between laboratories. It is recommended that visual damage should be used as the criterion, with the use of either the excrement weight method or the fabric loss method as a check. W.

**Mildew.** British Launderers' Research Association. *J. of Institution of British Launderers*, 1944, 25, 144. A short article dealing with the conditions under which mildew staining on fabrics may arise in the laundry and the effective treatment of such staining. La.

**Semi-stiff Collars.** British Launderers' Research Association. *J. of Institution of British Launderers*, 1944, 25, 177. A description of the types of semi-stiff

collars and a discussion of the faults which may appear in laminated collars during the laundering process. La.

**Bacterial Damage.** British Launderers' Research Association. *J. of Institution of British Launderers*, 1944, 25, 207-8. Bacterial damage may occur to wool and, to a lesser degree, cotton if goods are left in a damp condition. In one instance quoted, bacterial damage was associated with mildew damage. La.

#### (D)—OTHER MATERIALS

**Asphalted Paper: Testing Water Resistance.** E. G. Mullen. *Paper Trade J.*, 1944, 119, *TAPPI*, 11-12. The "dry indicator" test for determining the rate of transudation of water through paper is accelerated five-fold by raising the temperature of the water from 73° F. to 100° F. In the test, the indicator is spread on the specimen and covered by a sealed watch glass and the assembly is then left on water until there is an easily perceptible colour change over the entire area under the glass. Results are tabulated for 8 types of paper, including asphalted materials. C.

**"Flame-proofed" Paper: Inflammability Test.** Technical Association of the Pulp and Paper Industry. *Paper Trade J.*, 1944, 119, *TAPPI*, 39. Particulars are given of a revised test (*TAPPI* "Suggested Method," T461 sm-43) for assessing the inflammability of treated papers and paper boards from measurements of the "char length" and duration of "after-glow." C.

**Paper: Curling Tendency Test.** Technical Association of the Pulp and Paper Industry. *Paper Trade J.*, 1944, 119, *TAPPI*, 39-40. Particulars are given of a Tentative Standard test, *TAPPI* T466 m-44, for evaluating the tendency of sized papers to curl, in which a trapezoidal specimen is clamped at a definite angle across a hole in a float which is placed on water so that the under surface of the paper gets wet and its free end curls upwards. The angle through which the free end moves is read off on a degree scale and the time to reach the maximum is also observed. The length of paper that makes contact with the water is adjusted, by varying the size of the hole, so that the angle of curl comes between 30 and 60°. "Degree of curl" is the angle per centimetre of wetted paper. C.

**Paper: Water Vapour Permeability Test.** Technical Association of the Pulp and Paper Industry. *Paper Trade J.*, 1944, 119, *TAPPI*, 35-38. Full details are given of Tentative Standard test, *TAPPI* 464 m-44, for determining the rate of penetration of water vapour through sheet materials by the method in which a desiccating agent enclosed in dish by the specimen under test is exposed to an atmosphere at  $100 \pm 1^\circ$  F. and  $90 \pm 2$  per cent. R.H. and the gain in weight is plotted against time and the slope of the curve is translated into grams per square metre of surface per 24 hours. The humidity gradient (90—less than 5) is more controllable than that previously used. C.

**Inflated Rubber Sheet: Bursting Strains.** L. R. G. Treloar. *Trans. Inst. Rubber Ind.*, 1944, 19, 201-211. The two principal strains in a circular sheet of rubber clamped round its circumference and inflated have been measured at various points on the surface of the spheroidal balloon thus formed. The variations of the strains with position and with degree of inflation are discussed and it is found that the principal strains may show relatively large variations over an area in which the form is nearly spherical and the thickness is approximately constant. Observations of the bursting of sheets of various rubbers (natural and synthetic) are reported and photographs of burst samples are given. The general type of burst was one in which the inflated sheet developed a number of radial tears starting at the centre and terminating on a well-defined circle, the appearance resembling that of the petals of a flower. There appeared to be a general relation between the hardness at the instant of breaking and the number and regularity of the radial tears. From the strain measurements the conclusion is drawn that the radial tears are not caused by the relatively slight radial orientation of the molecules in the sheet. A detailed mechanism of bursting is suggested, in which the radial tears are compared with the radial cracks associated with glass fracture. C.

**Resins: Application in Paper Processing.** J. Y. Kao, L. Gold, A. Stull, R. Worden and W. Abramowitz. *Paper Trade J.*, 1944, 119, *TAPPI*, 22-27. A broad summary is given of the uses of resins in paper processing. The influence

of war demands is shown by a tabulation of military uses of processed papers. A similar list of civilian uses is given. Properties to be imparted to paper by finishing and materials available for various purposes are also recorded. The resistance of films of various synthetic resins to acids, alkalis, solvents, oils and greases, water vapour, gases, etc., is tabulated. C.

**Amthor Universal Tensile Strength Tester.** Staff of the Institute of Paper Chemistry. *Paper Trade J.*, 1943, 116, No. 6, p. 10-12. A report is given of a critical examination of the Amthor tester of maximum loading capacity 200 lb. The machine is of the pendulum type and has three ranges, 0-15, 0-50 and 0-200 lb., with scales graduated in tenths, quarters and whole pounds, respectively. The greatest error found by dead-weight loading was 0.54 per cent. of the full load. C.

## 7—LAUNDERING AND DRY-CLEANING

### (A)—CLEANING

**Bleaching Agents: Use in Laundries.** A. Foulton. *Wascherei-Ber.*, 1942, 10, 51-54 (through *Chem. Zentr.*, 1942, ii, 2960 and *Chem. Abstr.*, 1944, 38, 2827). A discussion of the various bleaches (such as oxygen, sun bleaching, chloride of lime, hypochlorites). The use of chloride of lime in laundries has been practically discontinued. By comparison sodium hypochlorite solution ("Bleichessenz") is safe and easily applied. Of critical importance to the appearance of the fibre are careful control of the bleach concentration and temperature (0.3 g./l. active chlorine; temperature 30° C., maximum 40° C.; bleaching time 15 min.). Thorough rinsing out of the washing solution prior to bleaching is important since soaps of olive-, peanut-, and soybean oils consume significant amounts of active chlorine. Tallow, coconut and palm oil soaps take up chlorine more slowly and in smaller amounts. By acidifying the bleach stabilized with alkali the bleaching activity is increased and also the danger of injury to the fibre. Sodium thiosulphate can be used to wash out unpleasant smelling chloramines. C.

**Naphthenic Acids and Soaps: Application.** —. Widaly. *Seifensieder-Zig.*, 1942, 69, 211-212 (through *Chem. Zentr.*, 1942, ii, 1864 and *Chem. Abstr.*, 1944, 38, 2837). Naphthenic acids produced in the refining of petroleum, particularly Russian and Rumanian petroleum, are finding increased use in the production of soaps and other derivatives for the textile industry, in combating pests, wood preservation, lacquer formulation, etc. In the impure state naphthenic acids form an almost black, viscous liquid with a pungent odour. Naphthenic acids with an acid number of 200-275, b.p. 240-300°, iodine number 0-12, and an unsaponifiable content of approximately 10 per cent. are most appropriate for soap production. The lower the iodine number the better are the acids. One means of obtaining naphthenic acids is by extraction with dilute (5 per cent.) caustic soda of the tar acids resulting from the sulphuric acid refining of petroleum. The unpleasant odour of the acids should be easily masked with lavender and similar materials. The esters may find use in perfumes. The analysis of naphthenic acids is limited mainly to the determination of water content, acid number, iodine number, and unsaponifiables. Recipes for several soaps are given. C.

**Tergin: Properties.** G. A. Bosurgi. *Riv. ital. essenze, profumi, piante offic.*, 1942, 24, 167-169 (through *Chem. Zentr.*, 1942, ii, 2550 and *Chem. Abstr.*, 1944, 38, 2838). Tergin consists, for the most part, of pectin and cellulose, and has a high capillary activity. Like soap, it penetrates into fibres and skin pores, emulsifies impurities and fat, and removes them adsorptively. It is a good soap-extender and an effective soap substitute. C.

**Shrinkage and the Cleaner.** *Information*, 1944, Sept. Shrinkage of woollen articles in dry cleaning may be caused either by solution of synthetic resins added to the articles to prevent shrinkage or by the presence of excessive moisture in the cleaning operation. Control of moisture is discussed in detail. La.

### (C)—FINISHING

**Calender Sheeting: Longer Life.** L. A. Bradley. *Ldy Age*, 1944, August, 37-9. Ten illustrated hints for extending the life of calender sheeting. La.

## PATENT

**Apparatus for Steaming and Drying Garments.** United States Hoffman Machinery Corporation. B.P.563,715; App. 21/7/42; Acc. 28/8/44. B.P. 564,369; App. 20/3/43; Acc. 25/9/44; Conv. (U.S.), 7/3/42. Apparatus for steaming and drying garments, comprising a base portion having a foraminous member supported thereon and encompassed by a permeable fabric adapted to be inflated inside the garment to be treated, and including means for passing heating fluids through said member, fabric and garment for steaming and drying them. The second patent adds improvements to the original one so that it is easier for an unskilled operator to finish the garments properly after only a very short period of training. La.

## 8—BUILDING AND ENGINEERING

## (A)—CONSTRUCTION AND MAINTENANCE OF BUILDINGS AND PLANT

**Plastics: "Heatronic" Moulding.** V. E. Meharg and A. P. Mazzucchelli. *Modern Plastics*, 1944, 21, No. 10, 108-113, 160, 162. Heatronic moulding involves heating a thermo-setting moulding material uniformly throughout its mass to about moulding temperature, transferring the hot and soft mass to the heated die without loss of plasticity, and then moulding the material in the usual manner. The heating rate, the relationship between the "pre-form" temperature and available transfer time, methods of measuring the temperature, the importance of uniformity of heating and methods of ensuring it, frequency, and precautions necessary in the final moulding operation are discussed. An indication is given of the various materials to which the heatronic process is applicable, the selection of equipment is briefly discussed, and the advantages of the heatronic process are pointed out. Examples of industrial parts now made by this method are mentioned. C.

## (B)—FIRE PREVENTION

**Mill Electrical Plant: Fire Risks.** *Silk & Rayon*, 1944, 18, 1008-1011. Electrical causes of fire in mills are broadly reviewed under the headings (1) friction, (2) arcing and sparking, (3) excessive current in conductors, (4) high resistance connections and (5) leakage of current. C.

## (C)—STEAM RAISING AND POWER SUPPLY

**Combined Heat and Power Plant: Advantages.** H. E. Partridge. *Textile Manufacturer*, 1944, 70, 364-366, 369 (from *Trans. Inst. Eng. and Shipbuilders in Scotland*, 1944, June, No. 1043). The writer condemns the practice of generating electric power as a separate undertaking and stresses the economic values of combining steam raising, hot water supply and power generation in one plant. Flow sheets are given of such a plant installed at a carpet factory which showed a thermal efficiency of 73.3 per cent. over a full week's run. It is not proposed that each small factory should have such a plant, however. An industrial town of about 30,000 to 50,000 people and, say, 20 factories would find one central station sufficient, with power, steam and hot water supplied from mains. C.

**Furnace Fuel Bed: Combustion Processes.** J. R. Arthur. *Bull. British Coal Util. Res. Assoc.*, 1944, 8, 202-207. A concise review is given of a selection of the work published during the past 30 years on combustion in fuel beds. The main headings are (1) The nature of carbon/air reactions, (2) Determination of the primary oxidation product, (3) The combustion of single particles, (4) Reactivity experiments, (5) Technical-scale experiments, and (6) Theories of combustion in fuel beds. C.

**"Niagara" Mechanical Stokers.** *Textile Weekly*, 1944, 34, 346-350. Drawings are given of the "Niagara" air draught stoker and fan forced draught furnace and their advantages as fuel economisers are discussed. C.

**Drainage of Steam Mains.** S. G. Saunders. *Industrial Heating Engineer*, 1944, 6, 125-9. Adequate drainage is of major importance when considering steam mains and their lay-out, and this article considers the main features of the provision of such drainage: Charts are included to give the condensation load when starting up from cold, and heat losses from bare pipes. Typical drainage arrangements are illustrated and described. La.

## (D)—POWER TRANSMISSION

**Rubber Couplings: Application in Power Transmission.** J. H. Booth. *Mech. Eng.*, 1944, 66, 389-391, 397. The physical characteristics of rubber in couplings, and the mechanics of power transmission by rubber couplings are discussed, with special reference to the coupling designed by F. M. Guy and incorporated under the name "Layrub" or "Thompson" in racing motor cars. C.

**Springs: Vibration.** W. A. Tuplin. *Engineering*, 1944, 158, 103, 124-125. The author presents a mathematical discussion of vibration in springs with non-linear characteristics. One of the conclusions drawn is that a shaft coupling with a non-linear spring characteristic is not a safeguard against excessive torsional vibration, but may actually combine the most dangerous characteristics of linear and non-linear spring systems. C.

**Bearings: Measurement of Adhesion Component in Friction.** B. W. Sakmann, J. T. Burwell, Jr., and J. W. Irvine, Jr. *J. Appl. Physics*, 1944, 15, 459-473. A study of the exchange of material between sliding surfaces uses a radioactive tracer method by means of which it is possible to detect quantities of metal as small as  $10^{-4}$   $\mu$ g. Spherical or hemispherical specimens were slid over an activated base surface. After the friction experiments, the riders were tested for the presence of radioactive material, and the quantity of metal deposited on the rider was determined as a function of various parameters. A copper-beryllium base surface was used with riders of steel, phosphor bronze, glass, copper-beryllium, nickel and other metals. It was found that the amount of base metal adhering to the rider was proportional to the load and increased with the distance of travel. Under otherwise identical conditions the amount of base metal deposited on the rider depended on surface finish and hardness of the rider. When the rider was harder than the base the transferred material increased with surface roughness. When the rider was softer than the base, surface finish was of secondary importance. Measurements made with steel specimens showed that the amount of metal deposited on them was inversely proportional to their Brinell hardness. For riders of different materials, but having the same hardness and surface finish, the amount of transferred metal increased with the solid solubility of the base metal in that of the rider. Lubrication decreased the transfer; the reduction depended on load and, for the same load, on the material of the rider. The influence of lubrication was greater for smaller loads. C.

**Lithium Stearate: Properties and Uses.** Foote Mineral Co. *Rev. Sci. Instruments*, 1944, 15, 157. Litholite (lithium stearate) is only slightly soluble in water, but capable of forming high-melting oil gels of great stability. It is therefore effective in lubricants capable of withstanding extremes of high (400° F.) and low (-90° F.) temperatures. The presence of other fatty acids and active ions such as Na, K,  $\text{SO}_4$  and Cl affects the performance of the greases. Lithium stearate transforms low-melting (below 50° C.) paraffins from a soft sticky mass to a tough rubbery material not likely to break or chip, tending to resume its original position after bending, and with a tensile strength approximately three times that of paraffin. Paraffin waxes containing 10 per cent. of Litholite have a melting point higher than carnauba, montan, or candelilla wax (approximately 85° C.). The lithiated paraffins are dust-repellent and, with their high melting point and shock resistance, suggest electrical applications. Preliminary tests indicate that the wax gels, used as paper coatings, have marked resistance to oils. C.

**"Thymotrol" Electronic Variable-speed Drive.** S. D. Fendley. *Paper Trade J.*, 1943, 116, TAPPI, 61-65. Illustrations and wiring plans are given of the General Electric Co. "Thymotrol" panel for the electronic control of motor speeds. When the "start" button is pressed, the motor will accelerate quickly to the speed corresponding with the setting of a potentiometer and remain at this speed irrespective of variations in load within the limits of the voltage drop compensation feature. When the "stop" button is pressed the anode contactor will be dropped out and a resistor connected across the armature to bring the motor to a quick stop as the full field is applied. C.

**Tubular Extension Shafts for Valve Operation.** G. H. Pearson. *Industrial Heating Engineer*, 1944, 6, 137-40. It is frequently desirable to be able to

operate a valve from a distance and the introduction of suitable gear produces a number of problems which are discussed in this article. These include strength and support of suitable extension members with particular reference to economy in material. La.

(G)—HEATING, VENTILATION AND HUMIDIFICATION

**Dielectric Hysteresis Heating: Thermal Conduction Problems.** H. Herne. *Wireless Engineer*, 1944, 21, 377-382. A brief review is given of the literature on problems of thermal conduction encountered in heating by dielectric hysteresis effects. The general equation of heat conduction is given and its solution for the one-dimensional case is obtained by a simple and direct method and also by a more powerful method based on Duhamel's theorem of temperature distribution with variable boundary conditions. Extensions of this theorem are indicated and applied to the problem of calculating temperatures in a pack of 14 sheets of wood when heated by radio-frequency currents. C.

**Textile Plant Control Instruments: Application.** W. B. Heinz and W. W. Starke. *Mech. Eng.*, 1944, 66, 451-455; *Textile Manufacturer*, 1944, 70, 407-410. A general discussion of the scope for instrument control in the textile industry, with special reference to water tank temperatures, drying and carbonizing plant, package dyeing machines, kiers, scouring bowls, and speed and tension control. C.

(H)—WATER PURIFICATION

**Water: Purification.** A. Meyer. *Leipzig. Monats. Text. Ind.*, 1942, *Fachheft* 2, 56-58 (through *Chem. Zentr.*, 1942, ii, 2222 and *Chem. Abstr.*, 1944, 38, 2318<sup>6</sup>). A discussion of the purification of water by filtration through gravel or sand, removal of iron, manganese and carbon dioxide by base exchange or flocculation and by working with screenless centrifuge, filter press, bag filter, Kelly and Sweetland presses and settling ("Anschwemm") filters. An illustration of a settling filter plant is given. C.

(I)—WASTE DISPOSAL

**Wool Alcohol Ointments.** O. J. Hedley. *Pharm. J.*, 1943, 151, 165 (through *Chem. Abs.*, 1944, 38, 1321). A wool alcohol ointment with greater firmness and "pull" than that of the British Pharmacopoeia (these *Abs.*, 1943, A415) is proposed. Its composition is wool alcohols 30 grains, hard paraffin 120, soft paraffin 90 and liquid paraffin 240 minims. W.

**Wool Alcohols: Base for Ointments.** T. D. Whittet. *Soap, Perfumery and Cosmetics*, 1944, 17, 94-96 (through *Chem. Abs.*, 1944, 38, 2165). W.

PATENTS

**Mouldable Fibre Compositions: Production.** British Cotton Industry Research Association, S. M. Freeman, F. Brownsett, Bakelite Ltd. and N. W. Knewstubb. B.P.563,627 of 22/10/1942:23/8/1944. In a process for the preparation of a composition containing fibres for the production of moulded articles, a mixture of fibres and a resinous binder, obtained by the method and apparatus of B.P.562,308, is subjected to heat and pressure. The resinous binder may consist of a natural or synthetic resin of the thermoplastic or the thermosetting type, e.g. a polyvinyl resin or a phenol- or urea-formaldehyde resin. When a phenol-formaldehyde resin is employed it may be either of the heat-hardening type or may consist of a mixture of a potentially reactive resin with a hardening agent, such as hexamethylenetetramine. The heated mixture of fibres and resinous binder may be subjected to mechanical pressure between calendering rollers, and the consolidated product moulded in sheet or laminated form or disintegrated and moulded to form articles of more intricate shape. C.

**Air Filter.** J. Baron & Sons Ltd. and H. S. Greenwood. B.P.563,806 of 7/5/1943:30/8/1944. Improved means for filtering and distributing air in mills comprising a filter bag secured to the end of an air outlet pipe is characterised in that the material of the filter bag is woven with warp and weft of doubled or multiple yarns of jute and cotton. A suitable fabric is woven from 3s yarns and has 10 ends and 10 picks per inch. The air outlet pipe is preferably formed with a suspension flange which may be slightly bell-mouthed. The complete system for supplying and distributing filtered air includes a pipe trunk system having a number of depending branch outlet pipes adapted to receive and hold the filter bag. C.

## 9—PURE SCIENCE

**Polar Molecules: Orientation; Demonstration.** P. Pierron. *C. r. Acad. Sci.*, 1941, 212, 991-993 (through *Chem. Zentr.*, 1941, ii, 2926 and *Chem. Abstr.*, 1944, 38, 2311<sup>4</sup>). The material in question is intimately mixed with an alkaline viscose solution and the mixture is spun in the usual manner (platinum tube) into an acid precipitating bath (sulphuric acid plus sodium and zinc sulphates). Microscopic examination of the resulting fibre shows that with polar compounds the liquid is present in the interior of the thread, whereas with non-polar compounds the original homogeneity of the mixture can be observed. Non-polar compounds tested were aliphatic hydrocarbons and decalin; polar compounds included toluene, *o*-xylene, naphthalene, nitrobenzene, chlorobenzene, isomyl alcohol and tetralin. C.

**Proteins: Precipitation by Synthetic Detergents.** F. W. Putnam and H. Neurath. *J. Amer. Chem. Soc.*, 1944, 66, 692-697. Anionic detergents precipitate proteins only when the latter are in the cationic form and the maximum pH at which precipitation occurs is close to the isoelectric point. A quantitative study of the system crystalline horse serum albumin-sodium dodecyl sulphate has shown that precipitation is governed by the protein/detergent weight concentration ratio, pH, temperature and ionic strength. At low detergent concentrations the protein may be completely precipitated, whilst in regions of excess of detergent redispersion of the precipitate occurs. Dissociation of the protein-detergent complex by means of barium salts yields a protein which, as indicated by diffusion, viscosity and electrophoresis, is in a regenerated rather than in the native state. The mechanism of precipitation, and the potential application of detergents to the preparation and separation of proteins are discussed. C.

**Methyl Dilinoleate: Viscosity.** D. W. Young and R. E. Biertuempfel. *J. Amer. Chem. Soc.*, 1944, 66, 843-844. Viscosity measurements on a pure sample of methyl dilinoleate over a range of temperature from -40 to 212° F. are presented. A straight line is obtained by plotting kinematic viscosity as a function of temperature on the viscosity-temperature chart proposed by the American Society of Testing Materials (D. 341-37T). C.

**Cellulose: Effect of Ultra-violet Light.** R. A. Stillings and R. J. van Nostrand. *J. Amer. Chem. Soc.*, 1944, 66, 753-760. An apparatus for the ultra-violet irradiation of solids in powder form in various atmospheres is described, which provides for evacuation prior to exposure, continuous mixing and continuous analysis of gaseous products, and an account is given of a study of the action of ultra-violet light on cellulose. Cellulose irradiated in nitrogen with all possible precautions to remove and exclude oxygen showed considerable degradation (chiefly a drop in degree of polymerisation and  $\alpha$ -cellulose content, an increase in copper number and liberation of carbon monoxide and carbon dioxide), the amount of degradation increasing with lengthening time of exposure. These changes could not be explained simply by the presence of oxygen in the nitrogen or that retained in the cellulose at the start of the exposure. The rate of degradation increased with increased oxygen content in the atmosphere. The rates of change of chain length and copper number during irradiation in nitrogen did not correspond to the rates calculated on the assumption that the reaction was of the first-order type. Exposures of  $\beta$ -D-glucose and cellobiose likewise resulted in the production of carbon monoxide and carbon dioxide, but at a considerably slower rate than that for cellulose. No change could be detected in the reducing power of these sugars, but exposed samples showed an increased absorption of ultra-violet light. Cellulose irradiated in the absence of oxygen was left in an unstable state at the conclusion of the exposure, i.e., the changes which the cellulose underwent during irradiation continued to occur during storage when air was present, but ceased when air was absent. The post-irradiation effect was increased by raising the temperature to 70° and by replacing the air in the storage bottles with oxygen. A small portion of the increased post-irradiation effect at 70° was due to the temperature alone. The post-irradiation effect was deferred or produced at will by alternating the atmospheres several times between nitrogen and oxygen. If the time of storage in oxygen was sufficiently long, the post-irradiation effect came to an end. Cellulose which had been irradiated in the presence of oxygen still underwent the post-

irradiation reaction. However the effect was smaller and became almost negligible when the time of irradiation in oxygen was extended from four to ten days. Possible reaction mechanisms are discussed. C.

**Cellulose-Nitric Acid Compounds: Ultra-violet Absorption Spectra.** G. Champetier and R. Marton. *Bull. soc. chim.*, 1943, 10, 102-106 (through *Chem. Abstr.*, 1944, 38, 2483<sup>6</sup>). Absorption spectra between 2300 and 4350 Å. obtained by reflection are given for cellulose,  $2C_6H_{10}O_5 \cdot 2HNO_3$  (I) (from the reaction of nitric acid ( $d$  1.415) on cellulose),  $2C_6H_{10}O_5 \cdot HNO_3$  (II) (from I by drying over calcium oxide), and for nitrocelluloses containing 11 per cent. (III), 12 per cent. (IV) and 13 per cent. (V) nitrogen; I shows a band between 2570 and 2850 Å, and II at 2700-3050 Å.; but III, IV and V show no selective absorption, but an undulation of the curve. Compounds I and II are therefore chemical individuals. On treatment with water they regenerate a cellulose with the same spectrum as mercerised cellulose. C.

**Colour Aptitude Test.** F. L. Dimmick. *Textile World*, 1944, 94, No. 5, 84-85. Steps in the development of a "colour aptitude" test by the Inter-Society Colour Council (U.S.A.) are outlined. In its present form 50 coloured rectangles are arranged haphazard on a gray background and have to be matched within half an hour by loose chips ( $1\frac{1}{8} \times 1$  inch) taken one by one from a flat holder in which they are invisible. The tested chip is replaced at one end of the holder and this action expels the next chip from the other end. The set covers the range of Munsell chroma from 4 to 5, that is, the test is a "colourful" one. The whole apparatus folds up into a space of  $12 \times 18 \times \frac{3}{4}$  inch. Scoring is on a per cent. basis and the best matchers reach figures just above 90 per cent. Mention is made of plans to test large numbers of observers. C.

**Positive Displacement Flowmeter.** J. McAfee. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 303. A simple flowmeter which is applicable over wide ranges of temperature, pressure and stream composition consists essentially of a U-tube, one leg of which is a gauge glass and the other a reservoir for mercury, water or other liquid heavier than and immiscible with the flowing stream. The U-tube is connected to valves which in turn join the line carrying the stream to be measured. A third valve is introduced in the line between the connections to the U-tube. Before the gauge glass is connected, its volume between two convenient markings is determined. To measure the flow rate the valves are adjusted so that the oil (or other fluid being measured) is forced into the mercury reservoir, the mercury into the gauge glass, and oil out of the gauge glass into the main line. Since as much oil is forced out of the system as enters, the net rate of flow in the main line remains unchanged. The measurement itself consists in determining the time required for the mercury level to rise from one calibration mark to the other, thus filling a known volume. If the calibrated volume is  $V$  gallons, and the time required to fill it is  $t$  minutes, the rate of flow,  $R$ , in gallons per minute, is given by the equation  $R = V/t$ . The device can also be used for measuring gas streams if proper account is taken of the compression of the gas on the upstream side of the meter, a low-density scaling liquid is used, and the variation in liquid level is limited to a low value. C.

**Powdered Solids: Analysis by X-ray Diffraction.** L. K. Frevel. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 209-218. Chemical analysis by the powder diffraction method consists of matching the X-ray diffraction pattern of an unknown material with one or more standard powder patterns. This requires (1) a correct registration and measurement of the diffraction lines and (2) a careful interpretation and evaluation of these data as applied to chemical analysis. Complications involved in these operations are discussed. Absorption edges, fluorescence, resolution, absorption, preparation of specimen, validity of standard patterns, and classification of standards are considered. Powder diffraction data are given for various compounds, and applications of the method are discussed. Advantages of combining spectroscopic information with diffraction data are pointed out. C.

**Keratins: Comparative Chemical Study.** T. P. Salo. *Thesis, Univ. of Michigan*, 1942 (through *Biol. Abs.*, 1944, B, 8089). Existing methods for the analysis of amino acids in proteins have been investigated, and modified for investigating the amino acid composition of keratin hydrolysates. Tyrosine, tryptophane, phenylalanine, cystine, methionine, threonine, histidine, lysine and arginine

were determined, and also moisture, ash, nitrogen and sulphur. The results of the analysis of 18 different animal integuments (corrected for moisture and ash) are reported. The nitrogen content varies from 15.1 per cent. in turkey and duck fan to 16.57 per cent. in horsehair. Snake skin is lowest in sulphur content (1.9 per cent.), and dog hair highest (5.22 per cent.). The class *Reptilia*, as represented by a single specimen of snake skin, has the highest tyrosine content (6.64 per cent.). The class *Aves* has the lowest content of tryptophane 0.24-0.35 per cent.), and the class *Reptilia* the highest (1.2 per cent.). Goose fan is lowest in phenylalanine content (1.15 per cent.). The cystine contents of the integuments range from 5.56 per cent. in the snake skin to 18.31 per cent. in dog hair, in accordance with their sulphur contents. The methionine contents range from 0.43 per cent. in the duck fan to 1.33 per cent. in the wool of the mountain sheep. Histidine varies from 0.39 per cent. in the duck fan to 0.97 per cent. in grey fox hair; lysine varies from 1.87 per cent. in sika deer hair to 6.28 per cent. in snake skin. Arginine is highest in the Virginia deer hair (10.38 per cent.) and lowest in the duck fan (5.22 per cent.). For the mammalian hairs the average molecular ratios of histidine:lysine:arginine are approx. 1:4:10. The molecular ratios of all the amino acids to tryptophane were calculated, since, of the amino acids determined, this was present uniformly in small amounts. The ratios of cystine to tyrosine, and threonine to tryptophane in feathers were significantly higher than similar ratios for the other integuments. The various structures studied may be provisionally classified into 3 groups in accordance with the amounts of the various amino acids present:—(1) the hair of mammals, (2) the feathers of birds, and (3) porcupine quills, snake skin and human skin. Differences among the 3 groups have already been indicated by the work of Astbury and co-workers on the X-ray spacings of keratins from different sources. W.

**Livestock Insect Control.** E. G. Thomssen and M. H. Doner. *Soap*, 1943, 19, No. 11, 96-103, 117, No. 12, 131-141. A comprehensive account of the common flying and crawling insects that attack livestock, of their effect on the animal and on animal by-products, e.g. hides, hair and wool, and of methods of control, including the treatment of infested premises. A table gives the formulæ of various dips. W.

**Dry Grinding: Effect on Properties of Keratins.** H. R. Cohen. *Archives of Biochem.*, 1944, 4, 145-150. Wool and ox-horn keratin both yield water-soluble protein upon grinding. The fractions contain no tryptophan. The nitrogen content decreases in successive water-soluble fractions. The protein contains high percentages of dialyzable material, this indicating that the fragments are of small molecular size. W.

**Silkworm Eggs: Treatment with Hydrochloric Acid.** M. Craiciu. *Atti mem. accad. sci. Padova*, 1942, 57, 91-101 (through *Chem. Zentr.*, 1942, ii, 2922 and *Chem. Abstr.*, 1944, 38, 2754<sup>4</sup>). Hydrochloric acid has a chemical action on the egg membranes, since after treatment the carbohydrates and proteins become more soluble in water. The air channels are enlarged by hydrochloric acid so that respiration of the eggs is more intense and the development of the embryo accelerated. After acid treatment a larger number of amino acids are present in the egg proteins; these are necessary for the development of the embryo. The formation of vitellin is accelerated which also accelerates development of the embryo. C.

**Amylopectin: Synthesis.** W. N. Haworth, S. Peat and E. J. Bourne. *Nature*, 1944, 154, 236. The authors report the isolation from the potato of an enzyme system that converts glucose-1-phosphate into a polysaccharide which is certainly not amylose, but resembles amylopectin in all the tests so far applied. C.

**Cellulose: Aerobic Decomposition by Thermophilic Bacteria.** H. C. Murray. *J. Bact.*, 1944, 47, 117-122 (through *Chem. Abstr.*, 1944, 38, 2687<sup>9</sup>). Cultures of bacteria which attacked filter paper under aerobic conditions at 60° were inhibited under anaerobic conditions. A common difficulty in growing cultures of cellulose splitters aerobically is low humidity. Saturation of the atmosphere with water seems necessary for optimum growth. The use of 0.8 per cent. agar gave more intensive digestions than did higher concentrations. Placing a layer of non-inoculated 2.0 per cent. agar in the bottom of the Petri dish and then pouring on an inoculated layer of 0.8 per cent. agar permits the dish to be inverted for incubation. C.

**Cellulosic Fibres: Resistance to Micro-organisms.** L. A. Kusyurina. *Microbiology* (U.S.S.R.), 1941, 10, 752-761 (through *Chem. Zentr.*, 1942, ii, 2157 and *Chem. Abstr.*, 1944, 38, 2825<sup>5</sup>). The resistance of flax, hemp, jute and kenaph to *Myxococcus hutchinsonii*, *Cellvibrio vulgaris*, *Trichoderma lignorum* and thermophilic anaerobic cellulose bacteria was studied. Flax and hemp fibres are decomposed most rapidly, but kenaph and jute fibres are much more resistant. C.

**Asbestos: Hygroscopic Behaviour; Influence in Organic Analysis.** J. Lindner. *Ber. deut. chem. Ges.*, 1943, 76B, 701-708 (through *Chem. Abstr.*, 1944, 38, 2586<sup>4</sup>). Numerous experiments with washed and purified asbestos show that errors in the determination of hydrogen in organic compounds can often be traced to the hygroscopicity of the asbestos and the slow rate at which it gives off absorbed moisture. The data presented describe the attraction and retention of water to and by asbestos at various temperatures. C.

**Polarographic Analysis: Recent Developments.** J. E. Page. *Nature*, 1944, 154, 199-202. A concise review of the principles of polarographic analysis with special reference to its applications in biochemistry. C.

**Malt Extracts: Analysis; Application of Statistical Methods.** C. H. Goulden. *Cereal Chemistry*, 1944, 21, 159-171. It is pointed out that there is a very close relation between methods of analysis and experimental design and that a study of different methods of analysis may suggest new designs or changes in others. Covariance analysis is illustrated by a study of the correlation between total nitrogen and saccharifying activity of the malt extracts for 12 varieties of barley grown at 12 stations distributed across Canada. The procedure of splitting up degrees of freedom in the analysis of variance is described, and an example is given showing how the maximum amount of information can be extracted from an experiment in which one of the factors is tested at various levels. Reference is made to the possibility of simplifying calculations by careful selection of levels in a factorial experiment. C.

**Cellulose: Esterification by Acid and Acid Anhydride Vapours.** G. Champetier and M. Foex. *Bull. soc. chim.*, 1942, 9, 711-713 (through *Chem. Abstr.*, 1944, 38, 3125<sup>4</sup>). The extent of nitration decreases rapidly with decreasing nitric acid content of vapour, becoming nil below 66 per cent. Vapours of formic acid and acetic acid give low esterification, comparable with that obtained with the liquid acids in the absence of dehydrating agents. Vapours of acetic anhydride give a more vigorous acetylation than acetic acid; the degree of esterification increases with temperature, reaching 16.6 per cent. acetyl in 200 hours at 150° and 760 mm. C.

**Cellulose: Iodine Adsorption.** A. Boutaric and Suzanne Anglade-Thévenet. *Bull. soc. chim.*, 1942, 9, 782-785 (through *Chem. Abstr.*, 1944, 38, 3124<sup>9</sup>). Spectrophotometric measurements were used in studying the blue sorption product formed between iodine in potassium iodide and cellulose (ashless filter paper dissolved in zinc chloride and fuming hydrochloric acid). The concentrations of the three components were varied one at a time and the effect on the spectral absorption curves was noted. The effect of time was also studied. The interaction between cellulose and iodine is very different from that giving the nearly instantaneous blue coloration between starch and iodine. The cellulose-iodine reaction takes place progressively, and the optical density at the wave length 520 m $\mu$  increases with time and reaches a limiting value at the end of 45 minutes, which is maintained for several hours and then gradually decreases. With rising opacity, the colour of the system shifts further and further into the violet. Taken collectively, the data indicate that the cellulose-potassium iodide-iodine system does not obey Beer's law (which is obeyed approximately by the starch-iodine system). C.

**Cellulose: Iodine Adsorption.** A. Boutaric and S. Fabry. *Bull. soc. chim.*, 1942, 9, 835-840 (through *Chem. Abstr.*, 1944, 38, 3125<sup>2</sup>). Capillary rise measurements were made with ashless filter paper strips which permitted the study of iodine sorption by cellulose. There is a rapid rise of the colourless solvent to height  $H$  and a slower rise of the iodine to height  $h$  as shown by the formation of a reproducible blue zone.  $H$  and  $h$  were measured at various time intervals and  $H/h$  remained nearly constant. The Freundlich adsorption isotherm was approached in all cases. Adsorption, however, varied when varying amounts of potassium iodide, ethyl alcohol, methyl acetate, acetic acid, hydrochloric

acid or caustic soda were added to the iodine solutions. Detailed tabulated data are given.

C.

**Cellulose Acetate: Precipitation.** M. Takei and H. Erbring. *Kolloid Z.*, 1942, 101, 59-64 (through *Chem. Zentr.*, 1943, i, 513-514 and *Chem. Abstr.*, 1944, 38, 3125<sup>9</sup>). Titration of cellulose acetate in acetone, methylglycol acetate, dioxane, diethyl lactate, acetic anhydride, aniline, and dichloroacetic acid with methyl alcohol gave a practically constant value for  $\gamma$  of 0.69 for the relation between the nature of the solution and the methyl alcohol concentration required to cause precipitation, which may be ascribed to the de-associating effect of the methyl alcohol. With benzene and heptane for precipitation, the solutions may be arranged in three classes. Acetone, methylglycol acetate and dioxane showed the smallest  $\gamma$  value (about 0.2 for benzene), followed by diethyl lactate, acetic anhydride and aniline ( $\gamma$  value, 0.6), and finally by dichloroacetic acid ( $\gamma$  value, 0.8). This difference is ascribed to the formation of secondary particles of varying structure. The dielectric solvation numbers agree, almost without exception, with the  $\gamma$  values. The de-associating influence of methyl alcohol upon addition of solutions of cellulose acetate is shown by the turbidity curves. Upon complete titration of all fractions with benzene, the solutions with the smallest  $\gamma$  values show, as expected, a precipitation range which comprises a narrower concentration range than do solutions with larger  $\gamma$  values. The lim.  $\eta_{sp}/c$  values for acetone, diethyl lactate and aniline are given; aniline

$\xrightarrow{c \rightarrow 0}$  shows the highest and acetone the lowest value. These results show that the state of solution in the original solution of cellulose acetate cannot be deduced from the precipitability with methyl alcohol, whereas the results obtained with benzene give a better picture.

C.

**Cellulose Esters and Ethers: Acetone and Water Absorption.** L. Clément and C. Rivi  re. *Bull. soc. chim.*, 1943, 10, 386-396 (through *Chem. Abstr.*, 1944, 38, 2817<sup>8</sup>). Mixtures containing 80, 70, 60, 50, 40, 30, 20 and 10 per cent. by volume of acetone in water were allowed to stand several days with the cellulose derivative (100 c.c. with 10 g.) and the amount of water or acetone absorbed was determined by pressing out the solution in stages, and determining the composition of the expressed liquid by its density. When plotted against the volume extracted, the compositions of the expressed liquids obtained from one initial solution lie on a straight line, and compound formation is shown by the convergence of the lines for several solutions. The point of convergence is calculated from the equation of the straight lines. Each cellulose derivative formed two compounds, those for cellulose nitrate containing 2.2 and 1.1 mol. acetone per mol. and no water; cellulose acetate, 3 mol. acetone per 2 mol., and 3 mol. acetone+8 mol. water per mol.; cellulose triacetate, 3 mol. and 1.5 mol. acetone per mol., no water; ethylcellulose, 3 mol. acetone per 2 mol. and 3 mol. acetone+8 mol. water per 4 mol.; benzylcellulose, 2 mol. acetone per mol. and 1 mol. acetone+2 mol. water per mol.

C.

**Cottonseed Pigments: Nature and Properties.** C. H. Boatner. *Oil and Soap*, 1944, 21, 10-15 (through *Brit. Chem. Physiol. Abstr.*, 1944, A III, 444). In addition to gossypol, three further pigments have been identified in cottonseed, (1) a red pigment that appears to be a quinonoid oxidation product of gossypol, (2) an oil-soluble yellow pigment, and (3) a purple pigment, named "gossypurpurin," with bands at 525 and 560 m $\mu$ . The properties of these pigments are discussed.

C.

**Dextran and Levan: Electron Microscopy.** B. Ingelman and K. Siegbahn. *Nature*, 1944, 154, 237-238. Photographs ( $\times 30,000$ ) of dextran under electron-optical magnification of 7,000 show in places uniform thin threads 30-100 A thick, some of which display nodes about 800 A apart, i.e. at intervals of about 160 glucose units. The estimated molecular thickness of dextran, from physico-chemical evidence, is about 50 A. Levan, obtained by seeding fructose with a culture of *B. vulgaris*, shows at  $\times 35,000$  compact structures. In the ultracentrifuge, the preparation gave reproducible sedimentation constants of  $200-300 \times 10^{-13}$  and diffusion constants of  $0.2 \times 10^{-7}$ , corresponding with molecular weights of the order of 100 million.

C.

**Methylated Methylglycosides: Chromatographic Separation in End-group Determinations.** J. K. N. Jones. *J. Chem. Soc.*, 1944, 333-334. The method of "chromatographic" adsorption on activated alumina from solution in mix-

tures of ether and light petroleum is shown to lead to the quantitative separation of tetramethyl- from trimethyl-methylglycosides, a step that is often required in the determination of end-groups in methylated polysaccharides. By means of the new technique it is shown that the repeating units of methylated banana and rice starches have 26 and 33 glucose residues, respectively. C.

**Acrylate and Vinyl Chloride Resin Dispersions: Preparation, Properties and Uses.** A. Renfrew and C. F. Flint. *Trans. Inst. Rubber Ind.*, 1944, 19, 213-222. The preparation of aqueous dispersions of polymethyl methacrylate and polyvinyl chloride is briefly described and the properties of these dispersions and of films formed from them are compared with the properties of rubber latex and latex films. Dispersions of plasticised polymethyl methacrylate are rather unsatisfactory substitutes for rubber latex. Their main applications are for bonding and finishing in the textile industry. Suitably plasticised aqueous dispersions of polyvinyl chloride show promise as rubber latex substitutes. They can be handled by a technique similar to that used with ordinary rubber latex and yield films showing remarkably rubber-like properties. The films are strong, supple and water-resistant, but somewhat deficient in tear resistance, less extensible than rubber, and not suitable for use at high temperatures. The preparation, properties and applications of dispersions of mixed polymers of vinyl chloride and methyl methacrylate, and of the dispersions of polyvinyl chloride in plasticiser (e.g. tricresyl phosphate), known as "Welvic" pastes, are also discussed. C.

**Di-*p*-chlorophenyltrichloroethane Insecticide (D.D.T.): Production and Properties.** G. A. Campbell and T. F. West. *Chemistry and Industry*, 1944, 319. A brief statement of the history of di-*p*-chlorophenyltrichloroethane,  $(C_6H_4Cl)_2 \cdot CH \cdot CCl_3$ , and its remarkable insecticidal action. It is conveniently prepared by condensing chloral with *p*-chlorobenzene in sulphuric acid monohydrate. Production early in 1945 is expected to reach 1,700,000 lb. per month. Clothing impregnated with a D.D.T. solution of suitable strength withstands 6-8 launderings and can be worn 6-8 weeks before losing its toxic activity towards a wide variety of pests. C.

**Fatty Acids: Low Temperature Saponification in Anhydrous Systems.** W. Gallay and I. E. Puddington. *Canadian J. Res.*, 1944, 22, B, 76-89. Finely dispersed sodium hydroxide, suspended in mineral oil, was used to saponify fatty acids and fats in mineral oil solution. Saponification of the acids was carried rapidly to completion at 60° C. The properties of the resultant soap suspensions in oil are discussed. The degree of saturation of the fatty acids or fats is of importance in the viscosity of the suspension formed. Low molecular weight fatty acids down to acetic were also saponified by this method. Of various fats used, only mutton tallow was completely saponified at low temperature (60° C.). Finely dispersed calcium hydroxide in mineral oil suspension effects complete saponification of fatty acids in mineral oil solution at 50° C. and of mutton tallow at a somewhat higher temperature. The effect of degree of unsaturation, and the use of other fats are discussed. Small quantities of added water are shown to promote saponification. This procedure has also been used to prepare suspensions in oil of Al, Mg, Ba, Pb and Li soaps. Some properties of the suspensions are described. C.

**Linoleic and Linolenic Acid Glycerides: Preparation and Properties.** B. F. Daubert and A. R. Baldwin. *J. Amer. Chem. Soc.*, 1944, 66, 997-1000. 1-Monolinolein, 1-monolinolenin, trilinolein and trilinolenin were prepared by the action of linoleyl and linolenyl chlorides on glycerol. Physical and chemical characteristics of the products are reported. Warming curves show the existence of two polymorphic forms of each of these compounds. Bromination of the glycerides yielded crystalline bromides. Melting point data are given. C.

**Polyvinyl Derivative Emulsions: Preparation, Properties and Uses.** J. E. O. Mayne. *Trans. Inst. Rubber Ind.*, 1944, 19, 196-200. A general account is given of the production of polyvinyl acetate and various derivatives, such as polyvinyl alcohol and polyvinyl acetals, and of the preparation, properties and uses of emulsions of these products. C.

**Sodium Soaps: Recrystallization in Mineral Oils.** W. Gallay and I. E. Puddington. *Canadian J. Res.*, 1944, 22, B, 90-102. The effect of the following

factors on the recrystallization of sodium soaps in mineral oils is described: rate of cooling, acidity and alkalinity of the soap, polarity of the oil, additives such as glycerol, and external shearing forces. Non-polar mineral oil acts as an inert diluent and recrystallization is essentially that from a hot melt. The presence of polar compounds results in some solvent action on soap in the mesomorphic states, and the effect of shear on the form of the recrystallized soap in such systems is important. The preparation of a sodium soap lubricating grease is essentially a recrystallization of the soap, and the properties of the grease can be altered over a wide range by suitable adjustment of the factors during the recrystallization. C.

**Sodium Soaps: Recrystallization in Mineral Oils; Effect of Shearing Stresses.** W. Gallay and I. E. Puddington. *Canadian J. Res.*, 1944, 22, B, 103-108. High shearing stresses obtained by the use of the colloid mill are shown to bring about recrystallization of sodium soaps at temperatures above the plasticity point of the soap. Below this temperature a comminuting action only on the soap in suspension is obtained. The length of soap fibre produced in the recrystallization increases with increase in polarity of the oil and with decrease in viscosity of the oil. The fibre length increases rapidly with increase of degree of unsaturation of the soap. The addition of glycerol or fatty acid has little effect. The action of the shearing stress is discussed and the conclusion is reached that long crystals are produced by a shearing of the double soap molecules on slip planes between melted hydrocarbon chains. The recrystallization is thus induced on molten portions of the soap. C.

**"Gravity" Dialyser.** J. S. Falconer and D. B. Taylor. *Nature*, 1944, 154, 87-88. A description is given of an apparatus for dialysis at low temperatures in which the movement of the liquid that is required to increase the speed of dialysis is obtained by taking advantage of the greater density of the liquid that streams out of the sac. The advantage is that the apparatus is compact enough to stand inside a laboratory refrigerator. The sac is placed inside a vessel about 15 cm. long and 3.5 cm. diameter, drawn out at the bottom to a jet, about 0.4 mm. diameter. This vessel is supported in a vessel about 40 cm. high and 7.5 cm. diameter, containing the water. A syphon connects the inner and outer vessels. The process continues for 24 to 48 hours, until the dense salt solution has risen to the level of the jet. C.

**Lauric Acid Solution in Hexane: Interfacial Tension against Water; Ageing Effect.** A. F. H. Ward and L. Tordai. *Nature*, 1944, 154, 146. The interfacial tension between water and solutions in hexane of long-chain amphipathic substances (e.g. lauric acid) has been studied by the pendent drop method which permits continuous readings to be made without disturbing the surface. An effect of age is demonstrated; the tension falls rapidly at first and then slowly reaches an equilibrium value after some days. The final value is quickly reached by raising the temperature and the course of the change is modified by the presence of electrolytes in the water. C.

**Soap-Mineral Oil Dispersions: Fibre Structure.** W. Gallay, I. E. Puddington and J. S. Tapp. *Canadian J. Res.*, 1944, 22 B, 66-75. The texture and other physical properties of soap dispersions in mineral oil, or lubricating greases, depend largely on the degree of dispersion of the soap. Calcium and aluminium soap dispersions yield in general a very unctuous product owing to the small size of the soap fibres in these systems. Sodium soap dispersions show a wide range of texture from smooth to fibrous, and this is related to the dimensions of the soap fibres in the dispersion. The microscopic examination of these fibres is discussed and a novel dry slide technique is described. Photomicrographs are given. The effects of agitation, flow, and other mechanical treatments are considered and the growth of fibres by orientation and overlapping of smaller fibrils is described. The results of investigations, by means of the micro-manipulator, of dispersions of soap and of rayon, milkweed and sulphite pulp fibres in mineral oil are reported. The effect of glycerol, present in greases manufactured from fats, is shown to be essential for the production of long fibres in sodium base greases, and this effect is ascribed mainly to the ability of oil to wet the soap in the presence of glycerol. C.

**Colloidal Molecules: Viscosity.** H. Staudinger. *Chem.-Ztg.*, 1942, 66, 380-385 (through *Chem. Zentr.*, 1942, ii, 2891 and *Chem. Abstr.*, 1944, 38, 2547<sup>9</sup>). The investigations made to date in the field of the molecular colloids are summarised.

(The present paper is No. 300 in Staudinger's series.) The viscosity number for macromolecular substances, as for low-molecular substances, is a characteristic quantity which in connection with the molecular weight can give information concerning the form of the molecule. Numerous literature references are given.

C.

**Sodium Oleate Solutions: Viscosity.** G. Rossi and M. Ragno. *Atti accad. Gioenia sci. nat. Catania* [6], Pt. IV, Mem. 14, 8 pp., 1939-40 (through *Chem. Zentr.*, 1941, ii, 2927 and *Chem. Abstr.*, 1944, 38, 2545<sup>7</sup>). According to Einstein the viscosity of dispersed solutions obeys the law  $\eta = \eta_0(1 + 2.5v)$  where  $\eta$  and  $\eta_0$  are the viscosities of the solution and the solvent, respectively, and  $v$  = the volume of the dispersed substance per unit volume of the solution. According to the Duclaux and Nodzu modification of Arrhenius' formula  $\log \eta/\eta_0 = KC$ , where  $K$  is a constant and  $C$  is the molecular concentration. The viscosity was measured for a 3.5 per cent. aqueous solution of sodium oleate and for aqueous alcoholic solutions of various alcohol concentrations from 23.25 to 95.0 per cent. by volume. By calculation of the values of  $v$  and  $K$  and plotting them against the alcohol concentration of the solution it was found that the curves go through a distinct minimum at an alcohol concentration of 71.25 per cent. by volume. The experimental results show that the sodium oleate is surrounded by a layer of solvent which in the purely aqueous solution consists of water. From the decrease of  $v$  or  $K$  with increasing alcohol content the conclusion is drawn that the alcohol decreases the amount of water adsorbed by the sodium oleate particles. At the minimum neither alcohol nor water is adsorbed. At the higher alcohol concentration an adsorption of alcohol takes place.

C.

**Wheat Starches: Gel Strength; Varietal Differences.** R. H. Harris, L. D. Sibbitt and Harriet Toman. *Food Research*, 1944, 9, 83-88 (through *Chem. Abstr.*, 1944, 38, 2697<sup>2</sup>). Some varieties of hard red spring wheat produce starches of higher gel strength than others. The environment during the formation of the kernel has an influence upon this property of wheat starch.

C.

**Duboscq-type Fluorometer.** W. Koch. *Nature*, 1944, 154, 239. The writer describes a simple adaptation of the Duboscq colorimeter for dealing with fluorescence colours. The light source is a 220-volt "Hanovia" U-shaped burner. The radiation passes through a Wood's filter and water or saturated copper sulphate solution in a 500 ml. flask and thence to the two cups of the colorimeter.

C.

**Colour: Psychophysics.** Committee on Colorimetry, Optical Society of America. *J. Optical Soc. America*, 1944, 34, 245-266. This report deals with definitions of light and colour, colours assigned to objects, chromaticity, luminosity, determination of luminosity data, dependence of luminosity data on conditions of observation, individual variations of luminosity data, standard luminosity data, relative luminous efficiency, absolute luminous efficiency of radiant energy, luminous flux, energy, density and intensity, luminance, luminous emittance, illuminance, retinal illuminance, luminous reflectance, directional luminous reflectance, specular luminar reflectance, luminous transmittance, directional luminous transmittance, measurement of chromaticity, three-colour method of colorimetry, three-colour mixture and matching, three-colour mixture data for matching spectrum colours, non-negative colour-mixture curves, additivity of luminance for different colours, luminosity coefficients of colour-mixture curves, individual variations of colour-mixture curves, standard colour-mixture data, significance of standard data for non-standard observers, colour-mixture data in relation to theories of colour vision, tristimulus values, computation of tristimulus values of any colour, specification of chromaticity in chromaticity diagram, description of colour mixtures in terms of chromaticity diagram, achromatic stimuli, dominant wave-length and purity, and interpretation of chromaticity differences.

C.

**Cord Hanging in Festoons: Distribution of the "Slack."** E. H. Neville. *Phil. Mag.*, 1944, [vii], 35, 414-419. Under the title "Exercises on a Tight-rope," the author deals mathematically with the problem of how the slack in a cord is shared between the separate festoons when the cord is supported at intermediate points, as by a series of smooth rings. A general result is that "If a uniform rope that is almost tight hangs in festoons through any number of smooth rings, then, to a first approximation, the ratio of the length of slack in any festoon to the chord of the festoon is proportional to the square of the

horizontal span of the festoon." In a particular case the result is obtained that "If a uniform tightrope passes through any number of smooth rings which are all collinear or all in the same horizontal plane, then, to a first approximation, the length of slack in a festoon is proportional to the cube of the span of that festoon." C.

**Plasticized Cellulose Derivatives: Flow under Compression and Extension.**

D. D. Eley and D. C. Pepper. *Nature*, 1944, 154, 52. According to the place-exchange theory of plastic flow as applied by Eyring to polymers (1943), the rate of flow,  $\theta$ , should be related to the stress,  $f$ , by the equation  $\ln \theta = a + b'f$ . The authors have found, however, in a long series of measurements on a plasticized cellulose derivative over a stress range of 2-160 kgm. per sq. cm. and a temperature range of 16-100° C. (cylinders under compression and rods under stretch) that the equation only holds up to a certain stress value,  $f_0$ . In the range from a value of  $f$  of 4.6 kgm. cm.<sup>-2</sup> up to  $f_0$ , the "activation energy" for flow falls from about 30 k.cal. to about 11 k.cal. and then becomes independent of stress. In this lower region of stress the flow may actually be described by Bingham's equation for the flow of solid/liquid dispersions in capillary tubes,  $\theta = A(f - f_0)$ . The authors did not obtain any indication of a true yield value. Over a temperature range of 40° C., the "mobility constant"  $A$  and the intercept  $f_0$  depended on temperature in the same way. Strain-hardening was observed in rods under low stretch,  $\theta$  falling 20-30 fold over the initial 3-4 per cent. extension and reaching a steady value, as reported by Andrade for wires. No such behaviour was observed with cylinders under compression. C.

**Silk Cocoons of Different Races: Ratio of Sericin Fractions.** C. Manunta.

*Seta*, 1942, 48, 24-26 (through *Chem. Zentr.*, 1943, i, 582 and *Chem. Abstr.*, 1944, 38, 3138<sup>4</sup>). Sericin B precipitates from solution mainly at pH 3.6 to 4.0; sericin A is precipitated from the filtrate by means of alcohol. Sericin A contains up to 37 per cent. nitrogen, sericin B only 16 per cent. The content of melanine nitrogen in sericin B is five times as large as that in sericin A, the content of carbohydrates three to four times as large. The results of chemical analyses are tabulated. C.

**Cellulose-decomposing Bacteria: Action.** R. Y. Stanier. *Soil Science*, 1942,

53, 479-480 (through *Exp. Sta. Rec.*, 1943, 88, 305). The author has established conditions such that *Sporocytophaga myxococcoides*, *Cytophaga hutchinsoni*, and *C. rubra* all grew excellently in a mineral medium with filtered dextrose as the sole carbon source in quantities ranging from 0.1 to 0.5 per cent. The filtered dextrose did not exert a toxic effect on growth in the presence of cellulose, although with the higher concentrations of dextrose the attack on the cellulose was diminished, apparently because of a preferential utilisation of the monosaccharide. The similarity in the rates of cellulose, cellobiose and dextrose oxidation by *C. hutchinsoni* indicates that cellulose is decomposed by an initial break-down to, and subsequent oxidation of, the constituent monosaccharide. C.

**Cotton: Use as Culture Medium.** E. J. Bottcher and H. J. Conn. *J. Bacteriology*, 1942, 44, No. 1, 137 (through *Exp. Sta. Rec.*, 1943, 88, 305).

Because of the importance of soil actinomycetes in the production of antibiotic substances, attention has been directed toward the finding of a substitute for agar which would be a more satisfactory medium for the growth of the organisms. Materials investigated included sand, glass beads, gypsum blocks, and cotton. Cotton proved to be the most satisfactory; it can be saturated with a culture fluid, and although it does not form a gel, it gives the organisms a point of attachment and allows good aeration. C.

**Ozone: Toxicity; Influence of Nitrogen Oxides.** R. D. Watson. *Ind. Eng. Chem.*, 1944, 36, 559-561.

An account is given of experiments which have shown that ozone is the toxic agent in ozonized air, and that there is no measurable difference in the toxicity to *Sclerotinia fructicola* and *Escherichia coli* of ozone produced from pure oxygen and from air when used at the same concentration. Nitrogen oxides have no direct effect on the toxicity of ozone. Additions of nitrous oxide and nitrogen pentoxide to ozone have no influence on the toxicity of ozone to *S. fructicola* spores. Of the possible nitrogen oxides that might be produced by ozonizing air, only nitrous oxide and

nitrogen pentoxide could exist in the presence of ozone. Nitrogen pentoxide was produced by the ozonizers used in the experiments but oxides that form nitrous acid, nitrogen dioxide and nitrogen trioxide, were absent. Nitrogen oxides may affect the acidity of the test medium, in which case there could be an indirect influence on the toxicity of ozone to fungi. The acidity of the medium has a relatively unimportant effect on the toxicity of ozone over the pH range 4.3 to 7.95, but below 4.3 there is an interaction between ozone and the acid in the medium which results in a large decrease in germination of the treated spores. C.

**Humidity Cabinet.** F. Todd. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 394-397. A humidity cabinet for accelerated corrosion tests under extreme indoor conditions is described and shown in diagrams and photographs. It consists essentially of a vapour-tight jacketed cylindrical container with a conical bottom and top. The walls and bottom are heated by hot vapours of cyclopentane. The conical base of the cabinet is filled with water which is maintained at a constant level and the air used in the cabinet is preheated to the temperature of the cabinet and prehumidified to 100 per cent. before it enters the cabinet. Means are provided for automatically controlling the supply of air and water. The test panels are supported by hooks on concentric rings. The advantages of this design are pointed out and corrosion test data are given showing the differences in performance between this cabinet and a cabinet of conventional type. C.

**Starch Indicator Solution: Preparation.** W. S. Platner. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 369. For the preparation of a stable starch solution for use in iodometric titrations, including the Winkler determination of dissolved oxygen, a 20 per cent. solution of Na or K hydroxide, or the solid caustic alkali, is added with stirring to a suspension of about 2 g. of powdered starch in 300 to 400 ml. of water until a thick, syrupy, almost clear solution is obtained. About 30 ml. of 20 per cent. potassium hydroxide are required to treat approximately 2 g. of potato starch. The solution is allowed to stand for about an hour and then made neutral or slightly acid with concentrated hydrochloric acid. If acidity does not interfere with the proposed titration (the final sample in dissolved oxygen titration by the Winkler method is acidic), 1 ml. of glacial acetic acid is added as a preservative. A solution prepared by this method has been used over a period of 12 months without deterioration, mould growth, loss of potency, or production of reddish colour in iodometric titrations for dissolved oxygen. Tests have shown that this method of preparation yields a solution which develops and maintains greater depth of colour and has a sharper end point than starch solutions prepared by other methods. C.

**Wijs Solution: Stability.** F. A. Norris and R. J. Buswell. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 417. Wijs solution was stored at room temperature in 250-ml. dark bottles. The solution was prepared in the standard manner and contained 1.5 per cent. excess equivalents of iodine over chlorine. Iodine number determinations were made on linseed oil stored in an ice box. Over a total period of 505 days, the Wijs solution did not change sufficiently to cause a measurable difference in the iodine number of the oil. No measurable differences were found when the reagent was taken from bottles that had been previously opened. These results indicate that the solution can be stored for a year or more in small bottles which are opened as required. C.

**Chlorate Ion: Rapid Determination.** A. J. Boyle, V. V. Hughey and C. C. Casto. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 370-371. A rapid method for the determination of chlorate in cell liquor which is produced during the manufacture of chlorine consists of reducing the chlorate ion in 40 per cent. hydrochloric acid by volume with a standard ferrous ammonium sulphate solution. A few drops of a 10 per cent. solution of ammonium molybdate are employed as catalyst. The excess standard ferrous ammonium sulphate is then titrated with standard dichromate, using diphenylamine sulphate as the redox indicator. The method is accurate to within about 1 per cent. of the amount of chlorate present. It permits greater precision than the sodium arsenite-potassium bromate method. C.

**Dissolved Oxygen in Water: Determination.** I. M. Sillars and R. S. Silver. *J. Soc. Chem. Ind.*, 1944, 63, 177-179. Sources of error in the standard

Winkler method (addition of manganous chloride and potassium iodide to the acidified sample, and titration of the liberated iodine) are discussed and details are given of an improved technique (including electrometric titration), which reduces the sources of error and enables their effect at very low concentrations to be assessed statistically. Using this technique in a series of tests, the authors have found a standard deviation independent of the mean oxygen value of the sample of between 0.001 and 0.0025; i.e. the minimum oxygen content which can be significantly distinguished from zero is 0.004 c.c. of oxygen per litre. As some confirmation of the method, samples of known oxygen content were made by diluting oxygenated tap water in deaerated water, the residual oxygen content of which was obtained by a slight modification of the procedure. The measurements agreed with the known values to within the predicted accuracy, indicating that iodine was liberated in strict linear proportion to oxygen present at the concentrations used (0.01-0.14 c.c. per litre). C.

**Oxygen: Micro-determination.** M. Pollack, P. Pringsheim and Dolores Terwoord. *J. Chem. Phys.*, 1944, 12, 295-299. A method for the determination of small quantities of oxygen is based on measurements of the quenching of the phosphorescence of a dye adsorbed on silica gel. For measurements of the rate of oxygen production a current of purified nitrogen is passed through the system providing the oxygen and then through a tube containing the phosphorescent gel which is placed between the disks of a Becquerel phosphoroscope. The phosphorescent light passes into a photo-tube of the electron multiplier type and the amplified current is measured with a galvanometer. Details of the apparatus and procedure are given, and advantages and limitations of the method are pointed out. Results obtained in the measurement of oxygen production by algae and by electrolysis are shown graphically and discussed. C.

**Sulphate in Cellulose Esters: Determination.** C. L. Hoffpauir and J. D. Guthrie. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 391-392. A method for the determination of sulphate in cellulose nitrate is described which involves decomposition with nitric acid to which a small amount of perchloric acid is added after the initial stage of digestion. The sulphate in the digest is then determined by a method which depends on the fact that barium chromate dissolved in dilute hydrochloric acid reacts with sulphate ions to give a precipitate of barium sulphate and an equivalent amount of chromic acid which can be determined iodometrically after the excess barium chromate is precipitated by making the solution alkaline with ammonia. The method may also be used for the determination of sulphate in other esters of cellulose. Results obtained with various esters, with and without addition of known amounts of sulphuric acid, are given. C.

**Starch: Spectrophotometric Analysis.** R. W. Kerr and O. R. Trubell. *Paper Trade J.*, 1943, 117, *TAPPI*, 161-164. A method for the determination of amylose and amylopectin in starch is based on the fact that the former stains blue with iodine and the latter reddish-purple. The starch is stained under defined conditions and diluted to a 0.002 per cent. solution, the per cent. transmission of which is measured for wave-length 610 m $\mu$  at which amylopectin displays a minimum. This value is then located on a standard curve connecting transmission and composition of the mixture. The following values are recorded:

		Amylose.	Amylopectin.
Whole corn starch	... ..	25.5%	74.5%
Potato starch	... ..	25.5	74.5
Tapioca starch	... ..	20.0	80.0
Waxy maize starch	... ..	No amylose.	

The limitations of the method are discussed. C.

**Tannin: Determination in Water.** J. Haslam, J. S. Wilson and J. E. Edwards. *J. Soc. Chem. Ind.*, 1944, 63, 179-182. A modification of the Berk and Schroeder method for the determination of small amounts of tannin in hard water is based on the reducing action of the hydroxyphenyl group of the tannin substance on the Folin-Denis phosphotungstate and phosphomolybdate reagent. The reduction product, which is blue in alkaline solution, is determined colorimetrically. The precipitation of hardness salts is prevented by

the addition of sodium hexametaphosphate to the mixture of reagent and sample. Sulphides, ferrous salts and phenolic matter interfere seriously in the test, but sulphites, nitrites, ferric salts and silicates are almost without influence. Several samples of water used industrially contained comparatively large proportions of interfering phenolic matter. C.

**Esterified Pulp Fibres: Effects on Paper.** J. J. Harrison. *Paper Trade J.*, 1944, 119, *TAPPI*, 42-52. In extension of work by Bletzinger and Aiken on the effect of blocking the free hydroxyl groups of cellulose on its paper-making qualities, the author has investigated the acetates, butyrates and stearates of bleached Mitscherlich pulp. The esterifications are described and also the measurements of acyl content and degree of polymerization (D.P.). The stearates did not lend themselves to measurements of D.P. by the viscosity method for they were insoluble in organic solvents and in cuprammonium hydroxide, and the regenerated cellulose was also insoluble in cuprammonium. The original and the esterified pulps were beaten under standard conditions and made into sheets, and these were tested for (1) moisture regain, (2) hydro-expansivity (change of dimensions with humidity), and (3) strength. The results are fully recorded. They show that the hindrance to bonding (loss of strength) due to esterification increases and the hygroscopicity and hygro-expansivity decrease with the length of the ester chain, a low degree of substitution in the butyrates and stearates giving the same effect as a high degree of acetylation. The addition of acetone (which assists swelling) or benzene emulsion to the medium in beating helped to give better results with the acetates and butyrates but not with the stearates. C.

**Pulp-wood Holocellulose: Chain-length Distribution; Effect of Cooking and Bleaching.** J. E. Atchison. *Paper Trade J.*, 1943, 116, *TAPPI*, 243-254. Details are given of an investigation of the effects of cooking and bleaching on the chain-length distribution in the holocellulose of spruce-wood. It is shown that this carbohydrate fraction suffers very little degradation during isolation by a modification of the method of Van Beckum and Ritter (1937; alternate chlorination and extraction of the chlorinated lignin by a 3 per cent. solution of ethanalamine in 95 per cent. alcohol). The holocellulose and the pulps prepared from the same wood by the sulphite, soda, and sulphate processes were nitrated by means of a nitric-phosphoric acid mixture and the average chain lengths of the nitrates were calculated from viscosity data (acetone solutions) by Staudinger's rule. The nitrates were also fractionated and the degrees of polymerization (D.P.) measured on the fractions and insoluble residues. The holocellulose as it exists in the wood has an average D.P. of 1450, but is a heterogeneous mixture of products with either very low or very high D.P. On pulping the very short molecules disappear and there is some degradation of long molecules so that there is a net increase in the proportion of medium-length chains. This effect is more marked in sulphate pulping than in the soda or sulphite processes. Bleaching still further enhances the molecular heterogeneity. The use of sodium chlorite as agent for the isolation of the holocellulose was also examined, but there is evidence that the product suffered extensive degradation. C.

**High Polymers: Molecular Weight.** H. W. Melville. *Trans. Faraday Soc.*, 1944, 40, 217-220. The determination of the molecular weight of high polymers is discussed and some of the difficulties attending measurements by end group, osmotic, ultracentrifugal and viscosity methods are outlined. The fractionation of polymers and the importance of measurements of molecular weight distribution are briefly discussed. C.

**Foam-inhibiting Agents: Activity.** S. Ross and J. W. McBain. *Ind. Eng. Chem.*, 1944, 36, 570-573. Tests were made with the following foaming systems: 7.74 per cent. Aerosol OT in triethanolamine, 5.55 per cent. Aerosol OT in diethylene glycol, 34.0 per cent. triethanolamine oleate in triethanolamine, 1.55 per cent. Nacconol NR in water and 0.85 per cent. Aerosol OT in water. The foam inhibiting effects of 22 chemical agents when added in the proportion of 1 per cent. by volume of the original solution were determined. It was found that systems which have a chemical similarity in either solute or solvent, when compared with respect to the anti-foaming effect of the same additions, show a corresponding effect in three out of every four cases; when systems have a more complete chemical resemblance, the correspondence of

the effects is even greater. Complete correspondence is shown, for example between Aerosol OT in triethanolamine and Aerosol OT in diethylene glycol. Only four of the additives tried, namely ethyl oleyl glycol *o*-phosphate, tri-octyl tripolyglycol tetrapolyphosphate, ethyl phosphate and *n*-nonyl alcohol, were effective foam inhibitors for all five foaming systems. Some experiments on the effect of concentration indicated that in general an optimum concentration seems to exist for defoaming action, which optimum sometimes lies definitely above the solubility of the agent. The most pronounced foam inhibitors are preponderantly insoluble. The action of foam inhibitors in the bulk tests is compared with their action on single films of the foaming systems, and the spreading of additives on single films is discussed from the point of view of surface tensions. It is pointed out that more than one mechanism must be postulated to account fully for all types of foam inhibition by chemical agents. C.

**Co-polymerides: Chain Reactions.** R. Simha and H. Branson. *J. Chem. Phys.*, 1944, 12, 253-267. The kinetics of chain copolymerizations are developed for reactions consisting of (1) an activation of stable monomeride; (2) a growth of activated polymer radical by monomeride addition; (3) a stabilization of the growing chains by (a) monomeride addition, (b) growing polymeride. The existence of a steady state in respect to the concentration of growing chains beyond the induction period is assumed. The rate constants of growth and termination will in general depend upon the individual composition and upon the nature of the activated chain end. Equations for the rate of change of mole ratio of the two monomeride species are developed in terms of mean rates of growth and termination obtained by averaging the actual rates over the distribution of growing polymeride. The equilibrium conditions lead to a set of difference equations for this distribution. The authors have examined the solution and results derived therefrom to see if they are of a form which permits a determination of the dependence of the rate constants for growth and termination upon the composition of the polymeride molecule. The influence of the type of active chain end involved on over-all rate and size distribution is considered. Various special cases are presented. Experimentally it is difficult to distinguish on the basis of kinetic data between the foregoing mechanism and one in which the rates of growth (and termination) for each of two kinds of monomeride depend solely upon the nature of the monomeride molecule added and are independent of the nature of the active chain end. Relations are derived for the molecular size distribution, the inhomogeneity of the copolymeride mixture in regard to composition, the average molecular weight, and the average composition of copolymeride as function of the composition of the monomeride residue. The importance of these results for soluble and insoluble copolymerides and for the theory of gel formation in vinyl-divinyl type polymerides is pointed out. C.

**Starch Hydrolyzates: Moisture Sorption.** J. E. Cleland and W. R. Fetzer. *Ind. Eng. Chem.*, 1944, 36, 552-555. Moisture equilibrium data have been determined in absorption and desorption for corn syrups and sugars by a method in which the sample was dispersed on diatomaceous silica and then exposed in a desiccator to air at various controlled humidities. The humidity of the air was controlled by passing it first through a bottle containing a saturated solution of a salt providing the desired humidity and then through bottles of sulphuric acid of such density as to yield air of relative humidity corresponding to that of the first bottle. Results are given in tables and graphs and briefly discussed. The amount of absorbed water is found to increase with dextrose equivalent and with increasing relative humidity. The data are compared with similar data for invert syrup and glycerol. C.

**Cellulose Acetates and Polymethylmethacrylates: Osmotic Pressure.** E. A. W. Hoff. *Trans. Faraday Soc.*, 1944, 40, 233-236. Osmotic measurements on cellulose acetates and polymethylmethacrylates in chloroform are recorded in the form of plots of  $\Pi/c$  against (1)  $c$  and (2)  $\Pi$ . Plots (1) are not rectilinear and (2) are rectilinear only for some of the cellulose acetates. In most cases, however, both kinds of plots can be extrapolated graphically to the same value of  $(\Pi/c)_0$  for the same substance. Plots of  $\Pi/c - (\Pi/c)_0$  are also given. C.

**High Polymers: Molecular Weight Measurements; Interpretation.** G. Gee. *Trans. Faraday Soc.*, 1944, 40, 261-266. A study of the theoretical basis of

the osmotic pressure relation  $(\Pi/C)_0 = RT/M$  shows that if  $(\Pi/C)_0$  can be found accurately, the absolute molecular weight of a polymer, as dispersed in the solvent which has been employed, may be calculated with complete confidence. Much the simplest and most widely used method of obtaining the molecular weight of long-chain polymers depends on the measurement of the viscosity of a dilute solution. Various attempts to calculate the viscosity of polymer solutions have led to equations of the general form  $[\eta] = KM^\beta$ . For essentially linear and approximately homogeneous polymers it appears that viscosity measurements can be used to measure molecular weights, once values of  $K$  and  $\beta$  have been found by calibration against the osmotic method. For linear polymers which are not homogeneous the viscosity method gives an average molecular weight for the mixture, which average, however, is not the same as that given by the osmotic method. When both osmotic and viscosity molecular weights have been determined, a comparison of the two gives a rough idea of the homogeneity of the sample. The viscosity method becomes of much less value when there is a possibility of the polymer being non-linear in structure. No reliable conclusions about molecular weight distribution can be drawn from molecular weight data alone, without carrying out a fractionation.

C.

**Crystalline Polymers: Melting.** Elizabeth M. Frith and R. F. Tuckett. *Trans. Faraday Soc.*, 1944, 40, 251-260. The thermodynamic equilibrium between crystalline and amorphous polymeric phases is discussed in terms of a fringed micelle model, as indicated by X-ray data. An expression derived for the melting point of a crystalline polymer is found to depend on the proportion  $\theta$  of amorphous material in the structure: this unsharp melting-point depends ultimately on a non-linear relationship between  $\theta$  and the free energy of the system. Calculated values of the crystalline-amorphous equilibrium ratio over a range of temperature are in good agreement with experimental data. An attempt is made to extend the calculations to the case of stretched polymers and a qualitative agreement is found.

C.

**Cellulose: Degree of Polymerisation.** O. A. Battista. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 351-354. Viscosity-concentration data are given for five samples of purified cellulose (viscose rayon, two rayon wood pulps, absorbent cotton and raw cotton), representing the degree of polymerisation range 300 to 3,000. On plotting the data on semilogarithmic paper, linear relationships were found in each case, between (1) the viscosity function  $\eta_{sp}/c$  and concentration, and (2) the relative viscosity function  $(\eta_r + 1)$  measured at 0.5 per cent. concentration and the degrees of polymerisation corresponding to values calculated from viscosity-concentration data extrapolated to infinite dilution. The data have been used to derive a mathematical expression by means of which the value of the relative viscosity function at the standard concentration of 0.5 per cent. may be converted to degree of polymerisation data equivalent to values obtained by extrapolation of viscosity-concentration data to infinite dilution.

C.

## 10—ECONOMICS

**Japanese Cotton Industry: Development.** *Textile Recorder*, 1944, 61, July, 40-41, 57. The writer discusses the present position and future ambitions of the Japanese cotton industry and quotes recent statistics of wages and production. In 1936 average wages for all male factory workers were 33.8 pence and for females 10.3 pence, per day of 9½ hours, and in the cotton industry about four-fifths of the operatives were females, with a large proportion under 16 years of age. Three firms handled 80 per cent. of the raw cotton.

C.

**Liverpool Cotton Association: Functions.** *Textile Recorder*, 1944, 61, March, 34-37. A brief account of the history of the Liverpool Cotton Association Ltd. and of operations on the Cotton Exchange, with special emphasis on their service to the cotton industry.

C.

**Plastics Raw Materials: Potential Supplies.** W. D. Scott. *Chemistry and Industry*, 1944, 274-278. The author raises the question whether the development of the plastics industry can be adequately supported by the chemical industry and concludes that a properly organized chemical industry can support a plastics industry many times greater than at present. The argument is based on the following tables of statistics: (1) Ratio of costs of the raw materials

of the plastics industry in the United Kingdom to those in the United States of America; (2) Ratio of labour, power, steam, coal and gas costs, U.K./U.S.A., (3) Costs of benzole recovery; (4) Output of olefines and aromatic hydrocarbons from a tubular steam cracking unit processing 600,000 tons of heavy naphtha per annum; (5) Coal utilization in Great Britain; (6) Comparison of methods for producing motor spirit; (7) Yields of chemical products from coal, at coke ovens and gas works and in the U.S.A.; (8) Yields of the various phenols on the basis of 65,000 tons of tar acids per annum; (9) Yields of tar acids and bases by the "hydrogenolysis" of Pittsburgh seam coal; (10) The potential production of alcohol, furfuraldehyde, cellulose, lignin, and vanillin from a recurrent supply of 200 million tons of waste cellulosic material, with figures for the production and industrial consumption of alcohol in the U.S.A. C.

**Textiles and Clothing: Production in S.E. Europe.** "*Planning*," 1944, No. 223, pages 3-16. This broadsheet raises the question of the restoration of the States of S.E. Europe and provides data on their economic development, under the headings (1) nutrition, (2) agriculture, (3) industrial development, (4) transport, (5) marketing and (6) finance. Under (3) figures are given for (a) the consumption of cotton goods, in kilos., per head of population, 1937, and (b) the percentage of people employed in the manufacturing industries whose work is in textiles and clothing: Yugoslavia (a) 2.0, Bulgaria (a) 2.8, Roumania (a) 2.2, (b) 26.1, Greece (a) 2.9, Poland (a) 2.3, (b) 25.5, Hungary (a) 2.4, (b) 24.5, Czechoslovakia (a) 4.2, (b) 22.5, Austria (a) 5.1, (b) 10.7. C.

**Textile Costing System.** H. M. Broadley. *J. Textile Inst.*, 1944, 35, P73-82. C.

**Textile Operatives' Earnings, 1944.** *Textile Weekly*, 1944, 34, 395. Wages at the end of January, 1944, are tabulated for various age groups and sections of the textile industry, and compared with wages in October, 1938. There has been an average increase in wages of 72 per cent. and working hours have risen from 45.8 to 47.3. C.

**Textile Wholesale Prices, July and August, 1944.** *Bd. Trade J.*, 1944, 150, 305, 341. The Index numbers for July and August are Cotton 159.3, 159.3, Wool 184.0, 184.0, Other textiles 133.7, 133.6, All articles 167.1, 167.5, (1930=100). C.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY, AND EDUCATION

**Operatives: Aptitude Testing.** *American Machinist*, 1944, 88, No. 16, 91-94. A brief illustrated account is given of methods for testing operatives engaged on assembling spark-plugs and selecting them for promotion to special duties. The tests are based on preliminary "job analyses" and observations on operatives of proved ability. C.

**Scientific and Industrial Research: Organisation.** *Nature*, 1944, 154, 249-252, 283-287, 311-314, 345-348, 373-377, 407-411. A critical review of recent discussions in England and the United States, including "A Post-war Policy for Science," by the Association of Scientific Workers; "Problems of Scientific and Industrial Research," from Nuffield College; the Symposium, "Organisation, Direction and Support of Research," by the American Philosophical Society; the "Goodenough" Report on Medical Schools; "A Scientific Policy for Agriculture," by the Parliamentary and Scientific Committee; various reports on Education, including Sir Ernest Simon's pamphlet on the Development of British Universities and the report of the British Association Committee on Post-war University Education; addresses by Lord McGowan and Mr. S. Courtauld; "Government and Industry: A Framework for the Future," by a Fabian research group; and Dr. D. W. Hill's "Impact and Value of Science." C.

**Textile Processing Research: Organisation.** American Association of Textile Chemists and Colorists. *Amer. Dyes. Rept.*, 1944, 33, 82-84. Recommendations are put forward for the reorganisation of the research activities of the Association. They include (1) a budget of about \$35,000 a year for the next five years, (2) the appointment of a permanent Director of Research, (3) more frequent publication of progress reports, and (4) establishment of research headquarters at the Lowell Textile Institute. C.

# THE JOURNAL OF THE TEXTILE INSTITUTE

## ABSTRACTS

### 1—FIBRES AND THEIR PRODUCTION

#### (B)—ANIMAL

**Merino Sheep: Control of Blowfly.** A. H. de Vries and J. C. de Klerk. *Fmg. in S. Africa*, 1944, 19, 485-495. Reference is made to previous articles on blowfly control (these *Abs.*, 1943, A555 and A675). The Australian classification of sheep into A, B and C types is described, A type having no folds, B type either medial or lateral folds, and C type prominent medial and lateral folds and other undesirable characters and being most susceptible to blowfly strike. Skin development on the tail is most undesirable, and Australian experiments have proved that skin development in the breech can be eliminated by breeding. Data are given on the availability of A type rams in S. Africa, and a breeding policy recommended. W.

**Sheep Blowfly Research. VII. Investigations in the Cape Winter Rainfall Area.** H. O. Mönnig and P. A. Cilliers. *Onderstepoort J.*, 1944, 19, 71-77. The investigation comprised the measurement of rainfall, temperature and humidity, the collection and identification of maggots from struck sheep and from the carcasses of sheep and various small animals, and trapping by means of ordinary meat bait. The live sheep produced mainly *Lucilia cuprina*, and the carcasses various species of *Chrysomyia*. W.

**Research as Applied to Animal Production.** R. B. Kelley. *Australian Vet. J.*, 1944, 20, 236-238. Research into domestic animal production in Australia should (1) determine characteristics and the range of genetic variability, (2) define and classify climate as the outstanding condition of the primary environment, (3) state the conditions of secondary or economic environments, and (4) co-ordinate the results by assessing the costs of production. Although major contributions have been made as broad surveys of the primary environment, no well-conceived attempt has been made to analyse existing data, e.g. to determine the suitability of particular breeds or strains of merino sheep for tropical environments. W.

**Research as Applied to Animal Production.** L. B. Bull. *Australian Vet. J.*, 1944, 20, 233-235. A discussion of the scope of ecology, physiology (functional and structural), nutrition and dietetics, and genetics and breeding as applied to the improvement of the healthy animal and its product. W.

**U.S.A.: Sheep and Wool Research.** W. R. Lang. *Pastoral Rev.*, 1944, 54, 262-263. The activities are listed of the Bureau of Animal Industry of the United States Department of Agriculture, especially those of the Western Sheep Breeding Laboratory, Dubois, Idaho, and the Southwestern Range and Sheep Breeding Laboratory, Fort Wingate, New Mexico. The latter deals with Navajo sheep. W.

#### (C)—VEGETABLE

**Cotton Plant: Variety Experiments in Georgia.** R. P. Bledsoe and E. D. Matthews. *Georgia Sta. Circ.* 140, 1943, 8 pp. (through *Exp. Sta. Rec.*, 1943, 89, 59). Coker 100, Stoneville 2B, and D. and P.L. were high in money value and lint yield per acre in north Georgia tests, 1938-42. Results were similar in 1940 and 1942, except that Coker 200 also yielded high. Three strains of Empire, a new variety developed by the station and U.S. Department of Agriculture, cooperating, were noteworthy in 1942 tests. Empire is of the Stoneville type, but has larger bolls, and higher lint percentage, and is early. Its lint length approximates to that of the above three leading varieties. In south Georgia tests, 1938-42, leaders in acre value included Coker 4-in-1, Coker Cleveland 7, and W. W. Wannamaker Cleveland Wilcox Resistant. Average results in

1942 resembled those of previous tests, except that Coker Cleve-wilt 7 yielded relatively lower than heretofore. The most promising new strains tested in 1942 were Wannamaker Stonewilt 18 and Bobshaw 1. C.

**Cotton Plant: Variety Trials.** R. S. Hawkins. *52nd Ann. Rept. Arizona Agric. Exp. Sta. for year ending June 30, 1941, 1942*, 99 pp. (through *Plant Breed. Abstr.*, 1944, 14, 195). Variety trials in 1940 showed that the varieties Delta and Pineland 44-51 out-yielded all others when grown in Upland regions, whilst Coker-Wilds 11 produced the longest fibre but the lowest yields. S × P yielded more heavily than the two other American-Egyptian varieties, P—S × P (Earlipima) and Pima. Some 1,300 F<sub>2</sub> plants of the Pima—120 cross and 60 plants of the F<sub>1</sub> back-cross (F<sub>1</sub> Pima × 120) × Pima, were grown with a view to selecting for a combination of fine linting, ability of the boll to hold the seed cotton, and productiveness. Crosses were made between the *G. barbadense* and Upland cotton hybrids on the one hand and Hopi × Stoneville hybrids on the other, in an attempt to combine the disease resistance of the *G. barbadense* type with the good quality of the other forms. Strength tests on the Stoneville cotton grown on the Yuma Farm show it to be stronger than any other cotton tested. The F<sub>6</sub> of the Stoneville × Hartsville cross was grown, and selfed seed obtained from those lines which showed promise. The progeny of crosses between Santan and many other varieties have been tested with a view to selecting a type possessing better lint and spinning quality than that variety. C.

**Manchurian Cotton: Improvement.** S. Nakatomi. *Plant Breed. News*, 1934, 9, 547-548 (through *Plant Breed. Abstr.*, 1944, 14, 227). Three selected strains obtained from a cross between a Manchurian cotton and a variety from southern China are illustrated in the original paper. They mature early like the native cotton which they surpass in ginning percentage and staple length. C.

**Station Miller Cotton: Characteristics.** H. B. Brown. *Louisiana Sta. Circ.* 29, 1943, 7 pp. (through *Exp. Sta. Rec.*, 1943, 89, 206). The strain of Station Miller cotton currently grown, according to test results, is a relatively good producer, has a medium large boll (60-65 per pound of seed cotton), is a good picking cotton with staple length 31-33 thirty-seconds of an inch, lint percentage 34-37, and considerable wilt tolerance, and the seed has a high oil content. It is considered desirable for hill lands in north Louisiana. C.

**Upland Cotton Kannô No. 1: Production and Characteristics.** S. Nakatomi. *Plant Breed. News*, 1934, 9, 544-547 (through *Plant Breed. Abstr.*, 1944, 14, 226). By line selection of an early maturing upland cotton, King's Improved, at Kantô-syu Agricultural Experiment Station, the new line, Upland Cotton Kannô No. 1, was obtained. It matures much earlier and is more productive than the parent type. It was thought most promising for southern Manchuria. C.

**Cotton Crop: Reduction of Labour and Power Requirements.** H. P. Smith. *Agric. Eng.*, 1943, 24, 149-150 (through *Exp. Sta. Rec.*, 1943, 89, 488). The principal means whereby the power and labour requirements of the cotton crop may be lowered are (1) the use of larger units and the performance of two or more operations at the same time; (2) mechanical thinning, hill dropping of mechanically delinted seed, and planting thin; (3) the treating of seed to obtain better stands, (4) shallow cultivation; and (5) the use of mechanical harvesting equipment. A suitable mechanical harvester in the plains areas would reduce almost by one half the total labour to produce a crop. In these areas a simple, cheap, stripper-type machine can be used satisfactorily. In sections where the plants grow larger and the harvest is earlier, a picker-type machine would probably be more suitable. C.

**Cotton Fields: Row Widths and Yields.** D. M. Simpson and E. N. Duncan. *J. Amer. Soc. Agron.*, 1942, 34, 544-552 (through *Exp. Sta. Rec.*, 1943, 88, 760). Review of row width experiments with cotton at several stations indicated that narrow rows yield more per acre, whilst wider rows yield more per row. Since planting and cultivating operations are done by the row, the number of feet of row per acre is important in determining production costs. Row widths may be varied from 2.5 to 4.5 ft. without materially changing cost of cultivation per row, and, in general, should be adjusted so as to result in the lowest cost per pound of cotton produced or the greatest production return for labour and equipment. In experiments at Knoxville, Tennessee,

1938-40, yields of cotton per row increased consistently and profitably as row widths were widened from 2.5 to 4.5 ft. Optimum row widths may depend upon local conditions regarding land value, labour and equipment costs. C.

**Cotton Plant: Effects of Ploughing and Seed Treatment on Sand.** H. P. Smith and M. H. Byrom. *Texas Sta. Bul.* 621, 1942, 16 pp. (through *Exp. Sta. Rec.*, 1943, 89, 257). On Lufkin fine sandy loam, a soil which tends to pack and crust after rains, better stands of cotton were obtained when the furrow for the seed was opened with a knife or runner-type furrow opener than when opened with either a narrow or wide shovel opener. It appeared that the knife opener gave better results, because it left a clean furrow and a firm seed bed with little loose soil. It did not disturb the soil enough to cause it to dry out as rapidly as when the furrows were made by shovel openers. A narrow shovel  $1\frac{1}{2}$  in. wide, with shields to hold the loose soil out of the furrow until the seed reached the bottom of the furrow, gave better results than a shovel 4 in. in width. The regular open centre press wheel used after covering the seed and in combination with a knife opener gave a slightly higher percentage of emergence than did other types of press wheels. Rolling on the seeds and pressing them in the bottom of the furrow before covering did not give any better stands than when the soil was pressed with an open centre press wheel after covering. All types of press wheels gave slightly better stands of cotton on the Lufkin fine sandy loam than those obtained when no press wheel was used. Cottonseed planted at a constant depth gave better stands and yields on the Lufkin fine sandy loam than did cottonseed planted at variable depths. Treatment of cottonseed with Ceresan was followed by significant increases in the emergence of cotton seedlings. Lime reduced emergence to some extent, while sulphur apparently had no effect on germination and emergence. C.

**Cotton Plant: Nutrient Uptake.** L. C. Olson and R. P. Bledsoe. *Georgia Sta. Bul.* No. 222, 1942, 16 pp. (through *Exp. Sta. Rec.*, 1943, 88, 760). The time and rate of absorption of plant foods by cotton were studied, 1939-40, under field conditions on three soils that are acid and low in base-exchange capacities, organic matter and mineral nutrients. At 120 days or longer after planting dry weight production and nutrient absorption was largely confined to the bolls. Some translocation of nutrients from plants to bolls occurred at the late growth stages. The amount of nutrients found in the cotton plant exceeded that ordinarily added in fertilizer mixtures, indicating the importance of plant residues in maintaining the fertility of cotton soils. The average amounts of nutrients found in the mature plants for all three soils approximated to N 104 lb.,  $P_2O_5$  38,  $K_2O$  97, CaO 132, and MgO 43 lb. C.

**Cotton Plant: Potash Requirement Test.** L. C. Olson. *Proc. Soil Sci. Soc. Amer.*, 1941, 6, 238-242 (through *Exp. Sta. Rec.*, 1943, 89, 180). Laboratory studies were carried on of soil reaction, clay content, available K, base-exchange capacity, and exchangeable bases. The available K in the soil prior to application of fertilizer was found to give a reliable index of the needs of the cotton plant for potash. The response from liming for cotton was found to be related to the amount of available potash in the soil. C.

**Cotton Plant: Response to Potash.** J. G. Futral and J. J. Skinner. *Georgia Sta. Bul.* No. 223, 1942, 15 pp. (through *Exp. Sta. Rec.*, 1943, 88, 739). Seven soil types were included in a comparative study of fertilizers that do or do not develop acidity, the latter having been neutralised with dolomitic limestone. The results indicate that neutralizing acid-forming fertilizers with dolomitic limestone does not materially affect the response or requirement for potash of the cotton plant. C.

**Cotton Soils: Effect of Sulphur Deficiency on Production.** O. R. Younge. *Proc. Soil Sci. Soc. Amer.* 1941, 6, 215-218 (through *Exp. Sta. Rec.*, 1943, 89, 184). Fertilizer treatments with sulphur and its effect on cotton production are reported for 10 soil types in the Coastal Plain of S.W. Arkansas. Six showed significant yield reduction where sulphur was not applied as compared with applications of 12 lb. of sulphur per unit of 4-10-4 fertilizer. Sulphur deficiency caused a marked reduction in the number of bolls produced, but boll size was not appreciably affected. Insufficient sulphur delayed growth, as indicated by the lower percentage of the yield being ready for harvest at the first picking. Sulphur deficiency had little effect on staple length, size of bolls, and lint turn-out. Yields of seed cotton and seed varied directly with the associated lint yield. C.

**Cotton Plants: Wilt and Root-knot Resistance and Effect of Potash Fertilizer.** *Bull. Texas Exp. Sta.* 627, 1943, 26 pp. (through *Rev. Appl. Mycol.*, 1944, 23, 225). In the sandy-loam fields of East Texas cotton yields are often seriously decreased by wilt (*Fusarium vasinfectum*), nematode root knot (*Heterodera marioni*), and potash hunger. Results of variety-fertilizer tests are reported. The data show that the use of a potash fertilizer increased yield and reduced wilt. Tests over a period of six years showed that the following varieties (arranged in decreasing order of likely value) were highly wilt-resistant: Coker 4-in-1, Coker 100 Wilt Resistant str. 39-5, Delta Dixie W.R. str. 2, Tifton Dixie Triumph, Dixie Triumph 25-12, Dixie 14-5 str. 2, Delfos 425, Miller 610, Delta-pine 12, and Stone-wilt. In addition, Coker 4-in-1, Coker 100 W.R. str. 39-5, and three strains of Dixie varieties were resistant to wilt and root knot together. Miller 610 lost much of its wilt resistance in the presence of root knot. It is concluded that farmers can prevent wilt and root knot from becoming limiting factors in cotton production by growing only those varieties that are resistant to both, using high-potash balanced fertilizers, and rotating cotton with *Crotalaria spectabilis* and sorghum. C.

**Cotton Root Rot Organism: Control by Sulphur.** A. A. Dunlap. *Phytopathology*, 1943, 33, 1205-1208 (through *Rev. Appl. Mycol.*, 1944, 23, 224-225). When thoroughly mixed with the soil and autoclaved, 325-mesh dusting sulphur, at the rate of one part per 1,000 of air-dry black Houston clay soil, totally inhibited the formation of sclerotia by the agent of cotton root rot, *Phymatotrichum omnivorum*, with no apparent effect on mycelial growth. At 1:2,000 the same mixture permitted only a trace of sclerotial growth, which proceeded unchecked, however, in the presence of a 1:8,000 concentration. The repressive action of the sulphur-soil mixture is possibly due to the formation of a toxic compound on autoclaving. C.

**Cotton Seedling Disease: Occurrence in West China.** L. Ling and J. Y. Yang. *Ann. Botany*, 1944, 8, 91-104. A species of *Colletotrichum* which differs from the conidial stage of *Glomerella gossypii* in morphological characters was noticed on diseased cotyledons and bolls of cotton in Szechuan Province, West China. It was considered to be identical with *C. indicum* Dast. Morphological and cultural characteristics are described and the results of investigations of the influence of temperature and pH on germination and growth are reported. The conidia are susceptible to desiccation. The production of toxic substances capable of causing blight of cotton seedlings was not confirmed. Artificial infection was successful on both Chinese varieties of *Gossypium arboreum* and American varieties of *G. hirsutum*. Soaking of seeds in conidial suspensions of the fungus resulted in a high percentage of diseased seedlings. Lesions on the cotyledons, young stems, young leaves, and detached bolls were induced by spraying with the conidial suspension. Besides cotton, fruits of pepper, tomato, eggplant, and pods of soybean and cowpea were successfully infected, but no plant included in the tests was found susceptible at the seedling stage. The fungus over-winters chiefly inside the infected seeds and possibly in the affected host tissues left in the field. Fairly high temperature in combination with high humidity favours the development of the disease, the latter factor being even more important under the conditions of cotton-growing regions of Szechuan. A rainy or cloudy period not only facilitates the dissemination of conidia, but also prevents the mucilaginous matrix from drying out; hence the conidia may survive for a longer period. C.

**Cotton Seedling Diseases and Boll Rots: Distribution and Dissemination.** U.S. Dept. Agric., Bur. Plant Ind., Soils, and Agric. Eng., *Plant Disease Rptr.*, 1943, Sup. 141, 53-78 (through *Exp. Sta. Rec.*, 1943, 89, 454). The following reports summarise the results of four years of surveys for cotton diseases and of special studies on distribution and dissemination suggested by observations made during the surveys: Occurrence of the Anthracnose Fungus, *Glomerella gossypii*, on Cotton Plants Grown from Infested Seed at Four Locations in 1941, by R. Weindling (pp. 59-65); Relation of Ginning to Contamination of Cotton Seed by the Anthracnose Fungus, by R. Weindling and P. R. Miller (pp. 65-72); and A Summary of Four Years of Cotton Seedling and Boll Rot Disease Surveys (pp. 54-58), The Dissemination of Fungus Spores from Contaminated Seed Cotton During Ginning in Relation to the Germination of the Seed and the Diseases of the Seedling (pp. 72-75), and The Probable

Effect of Humidity on the Survival and Sporulation of the Anthracnose Fungus on Cotton (pp. 76-78), all by P. R. Miller. C.

**Cotton Virus Disease: Occurrence and Control.** S. N. Moskovets. *Trans. Conference on Plant Virus Diseases, Moscow, 1940*, 173-190 (through *Rev. Appl. Mycol.*, 1944, 23, 213-214). Differences between the virus disease of cotton in Azerbaijan and the leaf curl occurring in the Sudan are pointed out. To avoid confusion of the two diseases it is proposed to name that in Azerbaijan "cotton curliness." Observations of reductions in the number of bolls caused by the disease and the susceptibility of different varieties are recorded. It is estimated that in years of severe infection susceptible varieties may suffer losses in yield up to 9.5 per cent. The disease also affects the quality of the fibre, reducing its length by about 7.5 per cent. and lessening its absolute strength by 3.3-16 per cent. The virus from cotton was successfully transmitted by *Aphis gossypii* or by infusing infected sap into decapitated stems of healthy plants to *Gossypium barbadense* and its variety *maritima*, and to *G. hirsutum*; similar symptoms were produced on *Hibiscus cannabinus* and *Solanum dulcamara*. Experimental data showed that under local conditions *A. gossypii* is the most important vector, *A. laburni*, *Myzus persicae*, and *Epitetranychus althæae* playing a secondary part. The incubation period of the virus varied from 35 to 56 days. The results of field tests with isolation from insects pointed to the possibility of seed transmissions. Less disease appeared to occur in denser stands. Higher incidence in summer- than in spring-sown plants was at least partly due to higher temperatures of soil and air. Some cottons were resistant to the virus; the most promising among those bred in Azerbaijan are strains of *G. barbadense*, such as Giza 7 and 3782-1 (from Giza 12), and *G. maritima*, such as Nos. 1, 2 and 7, and among those bred in Russian Central Asia, 6081, No. 15, 263, 4623a, and 35-1. For the control of cotton curliness the author suggests the growing of resistant varieties, roguing of infected plants, separate harvesting from healthy and diseased plants to ensure healthy seed for the next year, and control of vectors. C.

**Cotton Virus Disease: Effects.** V. L. Ryjkoff and Mme. T. P. Ovcharova. *Trans. Conference on Plant Virus Diseases, Moscow, 1940*, 191-196 (through *Rev. Appl. Mycol.*, 1944, 23, 214-215). The anatomical changes produced by the virus disease of cotton found in Azerbaijan consist in a thickening of the leaf lamina, the presence of excessive starch in the lamina and petioles, underdeveloped bast fibres in the petioles, and underdeveloped roots which are poor in starch. The disease is considered to be a special type of yellows, although it lacks the hypertrophy and necrosis of the phloem usual in this group of virus diseases, and produces an unusual hypoplasia of the bast fibres. It differs from the leaf curl disease of cotton in the Sudan in the following points: in Azerbaijan the diseased leaves tend to curl upwards, the palisade parenchyma is more strongly developed than in healthy plants, no additional cylinders are formed in the stems and petioles, and the bast fibres are hypoplastic; in the Sudan the diseased leaves mostly curl downwards, the palisade parenchyma is either underdeveloped or not developed at all, and additional cylinders are formed in stems and petioles. It is suggested that the two diseases are distinct, and it is proposed to name that in Azerbaijan "leaf roll" and the virus causing it, according to K. M. Smith's classification, *Gossypium virus 2*, Verderevsky. C.

**Cotton Virus Disease: Effects.** L. K. Kara-Murza. *Trans. Conference on Plant Virus Disease, Moscow, 1940*, 197-202 (through *Rev. Appl. Mycol.*, 1944, 23, 215). In a physiological study of the Azerbaijan virus disease of cotton it was found that the leaves of diseased plants contain less total and albuminous nitrogen and both leaves and petioles have more carbohydrates, particularly starch, than those of healthy plants, the amount of carbohydrates in the reproductive organs and in the stem walls being, on the other hand, smaller; furthermore, the accumulation of dry matter is less intense, and the amount of chlorophyll smaller. C.

**Boll Weevil: Winter Survival.** R. C. Gaines. *J. Econ. Ent.*, 1943, 36, 82-84 (through *Exp. Sta. Rec.*, 1943, 89, 345). It was found in a limited number of records that the number of boll weevils in woods trash was associated with the number of boll weevils present in cotton fields during the following May and June. Since the correlations between winter temperatures and the

number of weevils in cotton fields during May and June were significant, the inference would be that ground trash affords an important shelter for the weevils during the winter. C.

**Calcium Arsenate Insecticides: Effect of Particle Size.** J. C. Gaines and H. A. Dean. *J. Econ. Entomology*, 1943, 36, 76-79 (through *Exp. Sta. Rec.*, 1943, 89, 339). A report is given of tests of a calcium arsenate preparation containing large particles, a calcium arsenate-sulphur-rotenone mixture, and commercial calcium arsenate against the boll weevil, bollworm, and aphids at College Station, Texas, and against the boll weevil and aphids at Tallulah, La. The special and the commercial calcium arsenates were equally effective against weevils at both locations, but the coarse material (special calcium arsenate) did not give as good control of bollworms at College Station as the commercial product. Both materials contained approximately the same percentage of water-soluble arsenic pentoxide. The special calcium arsenate-sulphur-rotenone mixture significantly controlled the aphids and increased the yield at Tallulah, whilst the aphids did not injure the cotton sufficiently at College Station for the mixture to increase the yields. C.

**Cotton Aphids, Bollworms and Weevils: Control.** J. C. Gaines. *J. Econ. Entomology*, 1943, 36, 79-81 (through *Exp. Sta. Rec.*, 1943, 89, 339). The yields indicated that calcium arsenate-rotenone and calcium-zinc arsenate mixtures were equally effective and better than calcium arsenate alone. The higher yields were due to aphid control in the first case and slightly better bollworm control as well as retarding aphid increases at least two weeks in the latter. In a second experiment alternate applications of calcium arsenate and lead arsenate, using two applications of lead arsenate during the peak of bollworm injury, gave good control of both weevils and bollworms. Losses in yields occurred when cryolite was used in this manner, because of the increased weevil injury. Two consecutive applications of either lead arsenate or cryolite at the peak of bollworm injury instead of calcium arsenate did not prove to be effective against weevils, thus causing a loss in yield. C.

**Cotton Seed: Delinting and Disinfection.** U. R. Gore. *Georgia Sta. Circ.* 141, 1943, 18 pp. (through *Exp. Sta. Rec.*, 1943, 89, 80). Anthracnose-infested seed averaged an increase of 159 lb. of seed cotton to the acre from Ceresan treatment. Machine delinting or reginning gave an increase of 167 lb. and reginning plus the chemical treatment an average increase of 250 lb. of seed cotton to the acre over the fuzzy, untreated seed. Planting of about 1 bushel of reginned seed per acre is recommended. Either New Improved Ceresan or Ceresan proved effective dusts for cotton seed, which may be treated at any convenient time and stored in a dry place until planted. It is a good insurance any season to treat with organic mercury dusts. Being poisonous, treated seed should not be fed to stock or sold for oil. Seed heated in storage or damaged seed of low vitality should not be planted. Ample planting seed should be saved, since 2-year-old seed is almost free from disease and seed will be available should replanting be necessary. C.

**Cotton Seed: Gin Delinting and Incidence of Disease.** S. G. Lehman. *Research and Farming [North Carolina Sta.]*, 1943, 1, *Prog. Rept.* 2, pp 5, 6 (through *Exp. Sta. Rec.*, 1943, 89, 454-455). Reginning to remove the linters has been found to carry off much of the load of fungus spores and bacteria adhering thereto, and subsequent treating of the seed with a disinfectant saves many seedlings that would otherwise die of disease, thus making possible a lower seeding rate. Supporting data are presented. C.

**Seed Cottons: Characteristics and Ginning.** W. S. Smith, W. J. Martin and N. L. Pearson. *J. Agric. Res.*, 1943, 66, 249-260 (through *Exp. Sta. Rec.*, 1943, 89, 59). Sixteen cotton varieties grown at Stoneville, Miss., 1936-37, differed significantly in the time (minutes) and net energy (watt-hours) required to gin either 30 lb. of seed cotton or enough seed cotton to produce 10 lb. of lint. The larger and more fuzzy-seeded cottons took longer and required more energy to gin than the smaller and less fuzzy-seeded varieties. Varieties with a high lint percentage required less time and energy to gin 10 lb. of lint than cottons with low lint percentage. Whilst lint percentage had little effect upon the energy needed to gin 30 lb. of seed cotton, an increase in lint percentage tended to increase the time. Strength of fibre attachment to the seed had no effect upon the energy requirement. C.

**Sea Island Cotton: Costs and Returns in Puerto Rico.** L. M. Géigel. *Puerto Rico Univ. Sta. Bul.* 61, 1942, *Span. ed.*, 41 pp. (through *Exp. Sta. Rec.*, 1943, 89, 494). Information from 140 Sea Island cotton plantings in 1939 and 210 plantings in 1940 was obtained. Analysis is made of the costs of production and the variations in and the factors affecting such costs and returns. Share-croppers planted 62 per cent. of the crop in 1939 and 71 per cent. in 1940. The average yields of seed cotton per cuerda (0.97 acre) and the average price of the seed per pound were 498 lb. and 8.7 ct. in 1939 and 674 lb. and 9.1 ct. in 1940. The average costs of production per cuerda and per quintal were \$29.67 and \$5.96 in 1939 and \$37.21 and \$5.53 in 1940. The net returns were \$13.68 and \$2.74 in 1939 and \$24.29 and \$3.59 in 1940. Growing costs per cuerda were about the same on soils of high, low or medium productivity. Tenure had no material effect on net returns. The farmers making the highest returns had yields above 700 lb. of seed cotton per cuerda, applied more than 400 lb. of fertilizer per cuerda, harvested over 95 per cent. of first-class cotton, cultivated relatively small- to medium-sized plantings, and used from 120 to 160 hours of labour in growing operations on the soils of high productivity and 120 hours on the medium and poor soils. C.

**Bast-fibre Plants: Fibre Content Determination.** G. Bredemann. *Faserforschung*, 1942, 16, 14-39 (through *Chem. Zentr.*, 1943, 1, 467-468 and *Chem. Abstr.*, 1944, 38, 3471<sup>4</sup>). A conventional method is described according to which the samples, after a suitable pretreatment, are subjected to a predigestion, a main digestion and a cleaning process by spraying them on screens. *Hemp*: the carefully cleaned male and female stems are boiled for 2 hours in sodium carbonate; the removed bark is calendered, boiled for 2 hours with 2 per cent. caustic soda at 2 atm. pressure and sprayed with water. *Flax*: boil 0.5 hour with 1 per cent. sodium sulphite; do not calender bark, continue as for hemp. *Nettles*: boil for 2 hours with 0.4 per cent. sodium carbonate, then continue as for hemp. The fibres obtained are pure. C.

**Cotton Bolls: Growth.** D. B. Anderson and T. Kerr. *Plant Physiol.*, 1943, 18, 261-269 (through *Exp. Sta. Rec.*, 1943, 89, 662). Daily and seasonal variations in the diameters of cotton bolls of the Rowden, Half-and-Half, Coker 100, Cook, and D. and P.L. varieties of upland cotton were recorded during the summers of 1940-42. Enlargement of young bolls was not inhibited by severe wilting of the parent plant. Full-sized bolls shrank in size when the parent plants were visibly wilted and regained their size during the night if low soil moisture was not a limiting factor. Degree of shrinkage of full-sized bolls was, in general, proportional to the severity of wilting of the parent plant. During periods of severe drought, shrinkage occurred later in the day and recovery during the night was partial or even entirely absent. C.

**Cotton Crop: Improvement in South East Missouri.** J. R. Paulling. *J. Amer. Soc. Agron.*, 1943, 35, 409-412 (through *Exp. Sta. Rec.*, 1944, 90, 42). Progress and accomplishments in the Missouri cotton improvement programme are reviewed for the period 1936-42. C.

**Cotton Plants: Tolerance to Soil Salts.** N. A. Henkel and S. S. Kolotova. *C. r. Acad. Sci. U.R.S.S.*, 1943, 39, 209-212 (through *Brit. Chem. Physiol. Abstr.*, 1944, B III, 123). When the leaf stems are immersed in various salt solutions, and the leaves are exposed to diffused daylight, yellow spots and patches appear after varying lengths of time, depending on the tolerance of the given variety to the salts. Leaves of plants grown in salty soils exhibit high tolerance, and yellowing appears only when the salt concentration of the leaf juice is much greater than that found in normal plants exhibiting an equal degree of chloroplast destruction. C.

**Vetches: Manurial Value for Cotton.** C. D. Hoover. *Soil Sci. Soc. Amer. Proc.*, 1942, 7, 283-289 (through *Exp. Sta. Rec.*, 1944, 90, 46). In vetch fertilizer experiments, 1939-42, on Grenada silt loam, drilling lime and lime-fertilizer mixtures under hairy vetch was superior to ordinary planting methods. Vetches so treated produced nitrogen equivalent to 36 lb. per acre of commercial nitrogen as measured by cotton yields. Lime drilled into soils deficient in calcium might increase the nitrogen content of vetch as much as one-third as compared with unfertilized vetch. Vetch with a high nitrogen content decomposed faster than that low in nitrogen. C.

**"Whole Cotton": Growing and Processing.** F. K. Cameron. *J. Elisha Mitchell Sci. Soc.*, 1943, 59, No. 1, 1-13 (through *Exp. Sta. Rec.*, 1943, 89, 662). A practical account of the growing and processing of the whole cotton plant for oil and  $\alpha$ -cellulose. Cotton is planted close some weeks later than usual in the locality, matures about 25-30 weeks after planting, and is cut and baled. Seed cotton comprises 60 per cent. of the mass of whole cotton, leaves 2 per cent., and the remainder is about equally divided between cusps and stems. Cultural, harvest and storage methods, production costs, preparation for processing, recovery of cottonseed oil and pulping whole cotton and costs, cellulose derivatives, and uses of cellulose from whole cotton are discussed. C.

**Cotton Root Rot: Effect of Rainfall.** W. N. Ezekiel. *Texas Acad. Sci. Proc. and Trans.*, 1941, 25, 63-68 (through *Exp. Sta. Rec.*, 1943, 89, 630). The greatest economic damage by *Phymatotrichum omnivorum* in Texas is in cotton fields, where root rot often kills the plants in areas so large as to be visible even from aeroplanes. From the statistical studies presented, the conclusions are drawn (1) that the final percentage of root rot within areas of favourable soils is almost exactly a linear function of the rainfall during the several preceding months, with the same amount of rainfall having a greater effect later in the season, and (2) that beyond an optimum amount for a particular month, additional rainfall will not cause further increase in the percentage of root rot. Rainfall more effectively promotes root rot later in the season because young cotton plants are resistant. The root rot fungus and the cotton plant are both affected by the rainfall in somewhat the same manner. In years of favourable rainfall, yields may be higher even in root-rot areas, but this higher yield is still very much less than would be obtained were the disease absent. The disease thus tends to equalise cotton production on the particular farms on which it occurs at the drought level, causing meanwhile a percentage crop reduction that approaches the percentages of plants killed by root rot. These factors explain why, when average figures over an area are taken, increased yields may be directly correlated with increased prevalence of root rot. C.

**Cotton Varieties: Resistance to Fusarium Wilt Disease.** V. H. Young and L. M. Humphrey. *Arkansas Sta. Bul.* 437, 1943, 23 pp. (through *Exp. Sta. Rec.*, 1944, 90, 64). This study revealed marked genetical differences among cotton varieties as to wilt resistance and yield, but indicated also that environmental factors may greatly modify the expression of these differences. Varieties susceptible under favourable conditions include some giving high yields, good staples and high gin turnouts, whereas others, such as Half-and-Half, are inferior in staple length. Clearly, no highly susceptible varieties should be grown under conditions favouring the disease. Another group comprises varieties such as some strains of Rowden, developed in Arkansas, that are "wilt tolerant." Except where conditions are extremely favourable to infection such cotton is believed to offer the best present solution to the wilt problem in the State. A comparatively small number of varieties exhibit very high resistance, but whilst none of those now available can compete with some of the less wilt-resistant varieties on non-wilt or low-wilt soils, where conditions favour the highest wilt incidence no other varieties will succeed. If cotton must be grown in such areas, it is recommended that only some highly resistant variety such as Rhyne Cook be used. C.

**Bollworm Eggs and Larvae: Natural Control.** R. K. Fletcher and F. L. Thomas. *J. Econ. Entomology*, 1943, 36, 557-560 (through *Exp. Sta. Rec.*, 1944, 90, 224). A report is made of investigations of certain of the biological factors affecting the eggs and first instar larvae of the bollworm and their relative importance in relation to the possible survival of early stages. Assuming that all the eggs and larvae that were not known to be destroyed by predators or parasites hatched and completed development, the conclusion is reached that not more than 61 per cent. of the eggs laid by the bollworm develop beyond the first instar under field conditions. C.

**Cotton Aphid: Control.** E. H. Floyd, I. J. Becnel and C. B. Haddon. *Louisiana Sta., Northeast Louisiana Sta. Biennial Rpt.*, 1941-42, pp. 27-31 (through *Exp. Sta. Rec.*, 1943, 89, 711-712). Yields of seed cotton in Louisiana per acre from plats treated in 1941 with calcium arsenate, 10 per cent. sulphur, and 0.5 per cent. rotenone; calcium arsenate; calcium arsenate and 1 per cent.

nicotine; and calcium arsenate, 10 per cent. sulphur, and 0.2 per cent. pyrethrins were 1,384.0, 1,258.4, 1,674.4, and 1,368.0 lb., respectively, compared with 1,269.6 lb. for the untreated check. In 1942, treatment with calcium arsenate plus 1 per cent. nicotine; calcium arsenate plus 2 per cent. nicotine; 1 per cent. nicotine and a proprietary dust; and calcium arsenate alone resulted in yields of seed cotton of 3,019, 3,035, 3,062, and 2,835 lb. per acre, respectively, compared with 2,970 lb. from the untreated check. It appears that nicotine used at 1 per cent. concentration in every application of calcium arsenate or at 2 per cent. in alternate applications is equally effective.

C.

**Cotton Aphid: Damage and Control in Texas.** K. P. Ewing. *J. Econ. Entomology*, 1943, 36, 598-601 (through *Exp. Sta. Rec.*, 1944, 90, 223). In two experiments conducted at Waco, Texas, in 1942, it was shown that reductions in cotton yield of 164 and 243 lb., respectively, of seed cotton per acre, could be attributed to cotton aphids. Nicotine sulphate mixed with calcium arsenate to contain 0.5 per cent. of nicotine did not satisfactorily control the aphid. Calcium arsenate in alternate applications with calcium arsenate plus 2 per cent. of nicotine and calcium arsenate plus 1 per cent. of nicotine in each application gave considerable control of the aphid, the former being slightly better. Cryolite produced a lower infestation of aphids than did calcium arsenate. Early morning applications of calcium arsenate plus 1 per cent. of nicotine were more effective in controlling the aphid than were midday applications. A non-dusted buffer of 30 ft. or more greatly reduced the migration of aphids between plats.

C.

**Cotton Bolls: Effect of Boll Weevil on Production.** A. L. Hamner. *Miss. Farm Res. [Mississippi Sta.]*, 1943, 6, No. 6, pp. 4-5 (through *Exp. Sta. Rec.*, 1943, 89, 717). Cotton plants react to the loss of squares punctured by the boll weevil by setting a higher percentage of the young bolls and by producing heavier bolls. A higher percentage of young bolls that matured was produced on plants that had as few as 10 per cent. of the squares removed throughout the season than on untreated checks. When bolls were protected from weevil damage, fewer were required to make a pound of seed cotton on the treated plats than on the check. With the exception of a few bolls set early and late in the season, four varieties of cotton set approximately 80 per cent. of their crop during the first 5 weeks of fruiting and over 70 per cent. during the second, third, fourth and fifth weeks.

C.

**Cotton Insects: Control in Peru.** F. F. Bibby. *J. Econ. Entomology*, 1942, 35, 193-197 (through *Brit. Chem. Physiol. Abstr.*, 1944, B III, 127). The use of arsenicals, particularly calcium arsenate dust, for control of leaf worms on cotton produced a severe aphid infestation during the summer which could be prevented by using a cryolite (20 per cent.)-sulphur (80 per cent.) dust, or cubé root (0.75-1.5 per cent. of rotenone)-sulphur on an inert carrier instead. The rotenone-sulphur dust was suitable for controlling spring infestations of aphid. The Peruvian weevil, *Anthonomus vestitus*, was controlled with calcium arsenate or a cryolite-sulphur mixture, the latter being preferable as preventing subsequent aphid infestation. Sulphur alone or with nicotine sulphate to give a 2 per cent. nicotine mixture gave satisfactory thrips control. Arsenicals for leaf- or cut-worm should be used only as bran baits.

C.

**Mirid Bug: Control.** H. F. G. Sauer. *Arg. Inst. Biol. [São Paulo]*, 1942, 13, 29-66 (through *Exp. Sta. Rec.*, 1944, 90, 224). Investigations of the life history, habits, and control of the mirid bug *Horcius nobilellus*, conducted in the State of São Paulo, are reported. During the last 4 years this insect has caused severe losses in many cotton fields extending over a rather wide area of the State. Its injury is manifested by excessive shedding of small squares, blossoms and immature bolls and the suppression of fruiting branches. Technical descriptions are given of the adult and immature stages. Cultural control measures are recommended. The application of sulphur or a mixture of 80 per cent. sulphur and 20 per cent. Paris green or 66 per cent. sulphur and 33 per cent. calcium arsenate, as a dust, gives effective control if used at the rate of 12.5-16 lb. per acre, and 4-5 applications at 8-10-day intervals are employed when the population of the plant bug begins to increase more than 8 per cent.

C.

**(D)—ARTIFICIAL**

**Polyacrylonitrile Fibres: Spinning.** Y. Mamiya, S. Matui and S. Kanbara. *J. Soc. Chem. Ind. Japan*, 1941, 44, 125-126 B (through *Chem. Zentr.*, 1943, i, 802 and *Chem. Abstr.*, 1944, 38, 3481<sup>9</sup>). Acrylonitrile, bp. 77-80°, *d.* 0.807, was prepared and polymerised to a degree of 12,000-16,000. A 1.4 to 3.1 per cent. solution in Na or K thiocyanate was spun. Mixtures of lower alcohols, e.g. ethyl and propyl alcohols, were used as precipitation baths. Threads of 0.9-1.2 denier and *d.* 1.008-1.108 were prepared. The strength was up to 1.9-2.4 g./denier at 19-36 per cent. elongation. Dry heat up to a temperature of 130° does not damage the fibre, but causes shrinking; at 170° the fibre turns brown; decomposition begins at 215°. Hot water does not damage the fibre, but 1 per cent. caustic soda is injurious. C.

**Rayon Spinning Bath: Control of Composition.** A. Wehrung. *Chem. App.*, 1941, 28, 119-121, 132-137 (through *Chem. Zentr.*, 1941, ii, 2636-2637 and *Chem. Abstr.*, 1944, 38, 3468<sup>8</sup>). Various methods are described for the evaporation of the water which must be removed to insure a constant composition of the precipitating bath, or to crystallise the salt, and for recovering the components. During the evaporation process a part of the water is removed to facilitate the crystallisation, and the remaining part to maintain a constant composition of the bath. The ratio changes with the salt composition of the bath. The course of the evaporation and the expenditure of the reagents depend on the amount of the excess of the salt in the precipitating bath. Increasing the content of salt decreases the acid-salt solution in the newly formed fibre. The fibre so obtained is of a higher quality. Suitable apparatus is described and its costs given. Under mass-production conditions, it is economically practical to use the spinning bath for recovering the acid and salt. C.

**Viscose Rayon: Causes of Milky Striations.** W. Kling and H. Schwerdtner. *Textilberichte*, 1942, 23, 333-340 (through *Chem. Abstr.*, 1944, 38, 3468<sup>4</sup>). Commercial products were subjected to an extensive and thorough microscopic and chemical examination which showed that it is necessary to distinguish between a true and a simulated milky streakiness. The microscopic study of cross-sections showed that the true effect is characterised by the existence of a sponge-like hollow space between the outside layer and the nucleus of the fibre. A part of this hollow space appears to be filled with an organic substance, and the streakiness is increased by treatment with suitable extracting agents. A simulated milky streakiness may be due to various causes. A poorly desulphurised viscose rayon and several samples containing inorganic deposits, particularly zinc compounds, were studied. Chief causes of milky streakiness are (1) excessively high carbon disulphide concentrations during sulphonation, (2) insufficient ripeness of the viscose and (3) poor adjustment of the precipitation baths, particularly excessively high concentrations of sulphuric acid or zinc sulphate or excessively high temperature of the precipitation bath. The defect may be made more or less visible by washing, brightening and drying treatments. Thus, strong cleaning and brightening agents can make the defect more noticeable; on the other hand, fillers like mineral oil emulsions can make it less noticeable. C.

**Alkali-cellulose: Ripening; Effect of Metal Carbonyls.** G. A. Schröter. *Kolloid Z.*, 1943, 105, 223-225 (through *Chem. Abstr.*, 1944, 38, 3838<sup>5</sup>). Iron carbonyls, in gaseous phase, are absorbed by technical alkali cellulose (from beech and spruce sulphite pulps) and hasten the ripening process. At 40° the ripening time for beechwood alkali-cellulose was reduced by half, when the cellulose had an iron content (from the carbonyl) of 30 mg. per 100 g. cellulose. Nickel carbonyl gas was not absorbed to as large an extent as the iron carbonyl, and had less effect on the ripening time. Spruce sulphite pulp impregnated with nickel sulphate, dried, and then made into alkali-cellulose, ripened more rapidly than unimpregnated pulp. C.

**Viscose Solution: Mixed Molecular Chain State.** J. J. Stöckly. *Kolloid Z.*, 1943, 105, 190-199 (through *Chem. Abstr.*, 1944, 38, 3837<sup>9</sup>). In the various stages of viscose production, such as sulphiding, solution, ripening and decomposition, the "solution state" of the viscose plays an important role. A technical cellulose spinning solution is conceived as consisting of a mixture of bundles of esterified, etherified and solvated chain molecules, designated as

“mixed chain molecules.” The relationship between this concept and previous theories of solution state dealing with mesophases, myelin figures, and mixed little rods, is defined. The concept of mixed-chain molecules is in excellent agreement with the important phenomena observed in solution of the cellulose xanthate, in the process of ageing, in coagulation and in decomposition of the viscose, as well as with the properties of the regenerated cellulose. It also helps to clarify a number of hitherto confused and contradictory ideas on the preparation and spinning of viscose. C

#### PATENTS

**Water-soluble Polyvinyl Ester Filaments: Production.** R. P. Roberts, E. B. Johnson and H. H. Taylor. B.P. 563,960 of 21/11/1942: 7/9/1944. Filaments, foils and similar articles which swell or dissolve in water are produced by shaping and setting solutions of polyvinyl esters containing free hydroxyl groups in which the ester group content is between 2 and 12 per cent. of the maximum theoretically possible. Preferably the polyvinyl ester employed contains acetyl groups. The filaments are preferably produced by extruding an aqueous solution of the polyvinyl ester into a coagulating medium containing acetone, and it is also preferred to subject them to a stretching operation in the presence of a softening agent such as moist air or steam, in order to increase their tenacity. C.

**Rayon Staple Cutting Apparatus.** American Viscose Corporation. B.P. 563,983 of 12/4/1943: 7/9/1944 (Conv. 30/4/1942). Apparatus for cutting continuous filaments into staple fibre is provided with means for directing alternate cuts into separate discharge channels. Means may be provided for causing successive cuts to differ in length, each alternate cut of the same length being directed into the same separate discharge channel. The fibres of an individual cut may vary in length, alternate cuts of the same variation in cut being directed into the same separate discharge channel. The apparatus may comprise a rotatable member for feeding continuous filaments outwards therefrom, cutting devices disposed at a number of points about the rotatable member, and separate discharge channels associated with each of the cutting devices. Means may be provided for adjusting the position of at least one of the devices about the periphery of the member. C.

**Viscous Liquid Deaerating Apparatus.** British Cellophane Ltd. B.P. 564,153 of 16/7/1942: 14/9/1944 (Conv. 18/7/1941). Apparatus for deaerating viscous liquids under vacuum is fitted with means for determining the temperature of the (a) incoming liquid, and (b) the liquid just above the liquid level in the lower part of the container, and thermo-regulated means for controlling the vacuum. C.

## 2—CONVERSION OF FIBRES INTO FINISHED YARNS

### (A)—PREPARATORY PROCESSES

**Vertical Cotton Opener: Curling Action on Fibre.** *Cotton (U.S.)*, 1944, 108, No. 7, 128-129. The writer proffers answers to the question, “Does the vertical (Creighton) opener curl the cotton as it is swirled around while passing through the conical beater?” He claims that the Creighton opener is a more effective machine for cleaning than for opening, so that the position of the machine in the blowroom sequence is the ruling factor. He suggests as a satisfactory sequence: six blending feeders (two converted from a tandem feeder and two from a bale breaker), delivering 250-275 lb. of cotton per hour to a blending apron, a vertical opener, tandem lattice openers, and a Centrif-air machine. The action of the vertical opener is discussed and hints are given on its maintenance. C.

**Carding Engine: Speeds, Settings and Maintenance.** Textile Operating Executives of Georgia. *Textile World*, 1944, 94, No. 6, 98-99. Replies by the managers of twenty American mills (total spindlease 1,051,000) to a questionnaire on carding are analysed. They relate to (1) the beater speed for a blowroom system producing a 45-lb. lap, 13½ oz. per yd., every 6½ minutes, from ¾ in. Strict low middling cotton; (2) the relative merits of continuous, vacuum and hand methods of stripping; (3) grinding of cylinders, doffers and lickers-in; (4) the effects of reducing flat speeds from 3 to 1½ ins. per minute; (5) methods of checking waste and weight; (6) the merits of condenser drawing. Considerable divergences of opinion are revealed. C.

**Rayon Staple Fibre: Processing on Cotton Machinery.** F. S. Culpepper. *Textile World*, 1944, 94, No. 3, 70-73; No. 4, 116-117; No. 5, 109; No. 6, 119. Practical hints are given on opening, scutching, carding, drawing, speed frame processing and spinning of rayon staple, with particular reference to speeds and settings. Typical breaking loads are tabulated for various staples in singles yarn from 5s to 100s. The last instalment gives the complete organisation for spinning 30s. C.

**Slubbing Frame Roller Covers: Relation to "Eyebrowing."** E. H. Helliwell. *Textile World*, 1944, 94, No. 7, 66-67. The author discusses the conditions under which roller clearer waste becomes attached as "eyebrows" to speed frame products, thus causing slubs in yarn and cloth. He reports a test in which high-draft slubbing top rollers were covered with (1) plain calfskin, (2) calfskin embossed with a fine pebbly surface, (3) plain cork, (4) a composition with fine ground cork in it, and (5) a synthetic product, and, after "running them in" for a week, with stationary clearers, records were taken of (a) the weight of clearer waste per hour, (b) the place where the waste accumulated on the clearer, (c) the length of time that elapsed before the waste made contact with the strand, and (d) the nature of the waste. The data are tabulated. Under (a) there was little difference in the amount of waste, but under (b) it was found that coverings Nos. 3, 4 and 5 tended to deposit the waste at the front so that it hung down as a curtain and made contact with the strand more frequently than the doffing period. With the calfskin covers, the waste was carried well back, No. 2 even rather too far back, so that the waste could be dealt with easily at doffing time. Covers 3, 4 and 5 gave short, neppy waste, but with 1 and 2 the waste contained some long fibre. Some comments are offered on the use of revolving clearers. C.

**Roving: Variability.** *Cotton (U.S.)*, 1944, 108, No. 7, 129-130. The writer gives hank numbers obtained at four  $10 \times 5$  intermediate frames on two-process drawing from  $1\frac{1}{2}$  in. cotton. The extremes in 20 numbers are 0.878 and 0.922 (nominal, 0.9). C.

**Noble Comb: Criticism.** W. H. Robinson. *Wool Rec.*, 1944, 66, 276-277, 279-280. The Noble comb is discussed and improvements suggested. Oiling and greasing, and circle cleaning could be more satisfactorily done automatically, with consequent improvement in production. Intersecting sector circles could be tried, and, if successful, would both eliminate the dabbing brush and reduce the many detrimental effects which are directly due to the compression of fibres at the base of the pins by the force of the dabber. The use of drawing-off leathers is neither economical nor highly efficient, and methods should be investigated for increasing the life of combing leathers and for removing the combed fringes from the circle pins, forming them into a sliver, and transporting them into the coiler can. The following factors in Noble combing efficiency merit special consideration: the very small part of sliver between the two circles at the dabbing point which does not pass through the intensive final combing action; the danger of fibre breakage at the outside drawing-off roller point due to the compression of fibres at this point and the lack of a straight drawing-off action. W.

**Combing Machines: Comparison.** "Tex." *Wool Rec.*, 1944, 66, 236, 237, 239. A description of the distinctive features of Noble and rectilinear combs. W.

**Automatic Feed for Woollen and Worsted Cards.** Proctor & Schwarz Inc. *Text. World*, 1944, 94, No. 4, 122. The feed is driven by a separate electrically-controlled motor operated by a mercoide switch resting against the end of the scale arm. When the scale pan has received its weighing, the end of the beam rises and the switch falls forward, cutting off the current from the motor and stopping the spike apron. The drive dispenses with mechanical clutch mechanisms. The trap door over the scale pan operates in conjunction with the electrical control, by means of a solenoid and a spring mechanism. The weight of the mechanism on the scale arm has been greatly reduced. A compensating device located in the hopper ensures that an even amount of material is fed to the spike apron. Improved types of combing mechanisms and a beater with a receding-pin stripper motion are also incorporated in the feed. W.

## (B)—SPINNING AND DOUBLING

**Ring Frame Top Clearer: Modification to Prevent "Eye-browning."** *Cotton (U.S.)*, 1944, 108, No. 7, 130-131. The writer believes that a common cause of "eye-browning" with synthetic plastic roller cots on high-draft ring frames is that the clearer board is not heavy enough. He describes a modification that holds the waste for more than four hours without trouble. A piece of strap iron,  $16 \times 1\frac{1}{2} \times \frac{1}{8}$  ins. is screwed to the board and this is fastened to a bent rod that passes through a bracket mounted on the cap bar rod. The board will thus stand up by itself for attention to the rollers. The extra weight is about 1 lb. C.

**Spinning Frame Assignment Constants: Calculation and Application.** F. H. Gunther and M. Gross. *Textile World*, 1944, 94, No. 6, 95. The calculation of the number of frames required to feed a given number of looms is simplified by making a constant out of the ratio of pounds of yarn consumed per loom per working week to the pounds of yarn produced per frame. Thus, for a loom consuming 32.10 lb. of 17s weft per 40 hr.-week and a frame producing 410 lb. of the yarn, the constant is  $32.10/410 = 0.0783$ . To feed 225 looms would require  $225 \times 0.0783 =$  nearly 18 frames. C.

**Spinning Problems: Discussion.** Textile Operating Executive of Georgia. *Textile World*, 1944, 94, No. 7, 73-74; *Cotton (U.S.)*, 1944, 108, No. 7, 98-100. Replies to a questionnaire from a number of mills are reported on the following topics: (1) *Humidities in high-draft spinning.* A common figure is 55 per cent., but figures as high as 65-70 are also reported. (2) *Female doffers:* Few mills report satisfactory experience with female doffers. (3) *Synthetic products for roller covers:* Several mills report favourably, but recommend revolving front clearers to obviate "eye-browning." (4) *Scavenger rollers:* A variety of preferences are expressed for plush, paper and blue denim covers. (5) *Bobbin building:* Various types of winding and bunch building are discussed. C.

**Single Roving Worsted Ring Yarn Production.** Victor Ring Traveler Co. (U.S.A.). *Text. Mfr.*, 1944, 70, 305. Single-end roving in worsted preparation eliminates one drafting operation, reduces waste and increases production. A uniform sliver is produced by weighing (1) at the weigh box, and (2) at the first finisher, next to the weigh box. A table compares the layouts used in the single- and double-end methods for spinning 40s from fine wool (American grade). W.

## (D)—YARNS AND CORDS

**Hand-knitting Yarns: Production.** "K.M.G." *Wool Rec.*, 1944, 66, 366-367, 369. The production of hand-knitting yarns is described, with special reference to the suitability for different types of wool of the various preparing and subsequent processes. W.

## PATENTS

**Carding Engine.** D. Walsh. B.P.562,740 of 31/3/1943:13/7/1944. A carding engine is provided with means for passing a current of air beneath the rotating parts, i.e. the taker-in, card cylinder and doffer, to one end of the engine, the space through which the air passes being enclosed and having transverse baffles extending across the enclosed space from side to side of the frame, to prevent upward flow of the air to the rotating parts, thus preventing its interference with the carding operation, while enabling the air to convey the fly which is deposited on the baffles to the said end of the carding engine for discharge. Three co-operating baffles may be mounted under the rotating parts and devised to receive fly from the rotating parts and to direct it downward into the air current. The baffles may be made of thin material and capable of vibrating when the engine is working to assist the downward passage of the fly deposited on them. C.

**Carding Engine Eccentric Mechanism.** J. Pickles. B.P.564,035 of 4/3/1943: 11/9/1944. In eccentric mechanism for reciprocating the rubber rollers, leathers or like devices in carding engines, a non-metallic flexible coupling (either with or without a spring metal reinforcement) is provided between each eccentric strap and the co-acting cross-head of the shafts of the rubber rollers, leathers, or like devices. The eccentrics may also be provided with ball or roller bearings between the eccentric sheave and the eccentric strap. C.

**Drafting Mechanism.** Dominion Textile Co. Ltd. (Montreal). B.P. 564,188 of 7/9/1942:18/9/1944 (Conv. 3/9/1941). A drafting mechanism of the kind having a pair of small control rolls arranged behind the front drafting rolls close to the nip, and a roll for clearing the bottom control roll of waste is characterised by the provision of a pair of arms for holding the clearer roll yielding against the bottom control roll, supported on a member that is weighted to counter-balance the weight of the arms and of the clearer roll and is formed in two parts to which the arms are respectively fixed, whereby removal of the clearer roll is facilitated. C.

**Card Clothing Mounting Machine.** A. Abbey (Kardbeslag Fabriks Aktiebolaget; Norrköping, Sweden). B.P. 564,214 of 12/3/1943:18/9/1944. A machine for mounting fillets of card clothing on the drums or rolls of carding engines, includes a braking device for producing a certain tension on the fillet, characterised in that it is freely movable on a guide bar, and in that an auxiliary braking device is arranged in the path of the fillet to produce a pull on the portion of fillet between the braking devices, the pull acting longitudinally of the guide bar. The auxiliary braking device preferably comprises a braking disc provided with friction coating for the fillet. In order to adjust the braking force of the braking disc, it may be adapted to be forced at variable pressure against a stationary part and/or may be provided with means for varying the angle of contact between the fillet and the braking disc. C.

**Sliver Condensing Apparatus.** Dominion Textile Co. Ltd. (Montreal). B.P. 564,577 of 9/11/1942:4/10/1944 (Conv. 20/6/1942). In a method of condensing sliver of fibrous material, the sliver is continuously passed between a pair of condensing rolls having a groove and a mating tongue after the sliver has been first reduced in width to substantially that of the groove while being allowed to expand in a transverse dimension, the sliver while passing through the groove being condensed between the tongue and the groove and the side walls of the groove in the transverse direction. Apparatus for carrying out this method comprises in combination a pair of co-operating condensing rolls, a groove on one roll mating with a tongue on the other, and a member positioned adjacent to the rolls for the first condensing of the sliver, the member including a narrow sliver-constricting passage leading to the groove. Preferably, the member for the first condensing of the sliver has a funnel portion or tapering mouth forming an entrance for the sliver to the passage and is adapted to condense the sliver into a ribbon-like form and to retain it in this form until it enters the groove of the pair of condensing rolls. A large amount of the condensed sliver may be inserted into a can by packing the coiled sliver into the can under pressure. C.

### 3—CONVERSION OF YARNS INTO FABRICS

#### (A)—PREPARATORY PROCESSES

**Nylon Yarns: Preparation for Weaving and Knitting.** J. P. Ransom. *Cotton (U.S.)*, 1944, 108, No. 5, 85-88; No. 6, 93-96, 126; No. 7, 95-97, 136. Practical advice is given on twisting, twist setting, knot tying, single-end sizing, coning and oiling of nylon yarn. C.

**Nylon Yarns: Winding, Sizing and Weaving.** E. I. Du Pont de Nemours & Co. *Rayon Textile Monthly*, 1944, 25, 277-281. Practical advice is given on (1) suitable tensioning devices for winding, (2) knot tying, (3) single-end sizing, (4) oiling, (5) tinting and marking, (6) control of static electricity, (7) winding off dense packages, (8) warping, (9) tape sizing, (10) weft winding, and (11) weaving, of nylon yarns. C.

**Rayon Tyre Cord: Twist Setting by High-frequency Heating.** Industrial Rayon Corporation. *Textile World*, 1944, 94, No. 7, 105; *Rayon Textile Monthly*, 1944, 25, 285. A picture is given of the working bench at which rayon tyre cord on 18-lb. cones is passed through a high-frequency electric field whereby heat is generated internally. Each unit has an output of about 22,500 B.Th.U. per hour and can deal with several thousand pounds of tyre cord per 24 hours. C.

**Warping Combs and Reeds.** Frank Kaufmann. *Rayon Textile Monthly*, 1944, 25, 331-332. Brief descriptions are given of various types of comb and reed used in warp preparation, with illustrations of (1) the tape type of spring

extension comb, (2) the screw type ditto, (3) the positive expansion comb, (4) the fan reed holder and (5) a warp leasing device with swing comb for holding the split rods and hook reed. C.

(B)—SIZING

**Laboratory Tape Frame.** J. M. Cook. *Textile Research*, 1944, 14, 188-193. A laboratory tape frame for small lots of cotton warps consists of a narrow steel frame approximately 36 in. high, on which are mounted the guide rods, combs, squeeze rollers, and leasing rollers. The size box and drying chamber are attached to the frame between the floor and the top. On the T-shaped front of the machine is mounted a movable carriage, equipped with rollers that allow it to be rolled from side to side on the frame. Bearings for the loom beam, a variable speed drive, and bearings and shafts for driving the squeeze rollers are mounted on this carriage. The variable speed drive permits the slashing of yarn at speeds ranging from about 4 to 23 yards per minute. Yarn bobbins from the spinning frame are placed in the creel and the yarn is pulled between polished guide rods mounted at the rear of the machine and through a comb made from a fine shortened reed. It then passes over a roller, through the size box, between squeeze rollers and over and under rollers in a drying chamber in which the temperature of the air is controlled by a thermostat. The dried yarn then passes to lease rollers, through an expansion comb, and on to a loom beam. The beam is of the usual diameter, but is constructed in sections, the sections being separated by aluminium discs. The size box consists of an inner copper shell, an outer shell, and a wooden box in which the shell rests. The outer shell contains glycerin in which is submerged an electric heating element which is thermostatically controlled. The squeeze rollers are about 3 in. in diameter, the bottom one being driven from the loom beam and the top one being covered with rubber about  $\frac{3}{8}$  in. thick. Photographs, diagrams and notes on the use of this machine are given. C.

**Rayon Crêpe Yarn: Dressing.** S. J. Miller. *Textile World*, 1944, 94, No. 6, 113. Practical hints are given on the dressing of rayon crêpe yarn to secure uniformity in the fabric. Particulars are given of four mixtures of oil and size (gelatin) for soaking and a table shows which recipe is appropriate for each of a wide range of crêpe yarns. C.

**Rayon Warp: Sizing; Tensions and Stretch.** J. J. Sussmuth. *Rayon Textile Monthly*, 1944, 25, 283. The author discusses the importance in rayon sizing of controlling the three tensions (a) from the warp beam to the point where the size is applied, (b) from this point to the first drying cylinder and (c) from the last cylinder to the weaver's beam. C.

**Sweet-potato Starch: Application.** C. W. Bendigo. *Textile World*, 1944, 94, No. 6, 123. It is reported that plant for the production of more than 100 tons of sweet-potato starch daily is under construction in Florida. Experience during the past 10 years in the application of the starch in sizing is briefly reviewed. It appears to give best results on fine yarns, but has been used to good effect on 20s. Suggested recipes for (a) difficult and (b) light warps are, for 100 gallons:—starch (a) 120, (b) 80 lb.; tallow (a) 6, (b) 4 lb.; size taken up (a) 7-12, (b) 6-9 per cent.; cooking time, 2 hours; storage temperature 180° F.; sow box temperature, 205° F.; squeeze roller, 210 lb. C.

**Tape Frame: Automatic Control.** Tallassee Mills Inc. *Textile World*, 1944, 94, No. 7, 64-65. An illustrated account is given of steps taken to secure (1) elimination of excessive stretch in the warp, and (2) tension control and consequent regularity of beam density, by fitting Reeves variable-speed transmission units at (1) the main drive of the tape frame, (2) the size rollers, and (3) the loom beam, and placing these units under control from the Brown "Moist-o-Graph" moisture recording panel. C.

(C)—WEAVING

**Loom Reeds: Selection.** H. E. Wenrich. *Rayon Textile Monthly*, 1944, 25, 284-285. Practical hints are given on the selection and care of pitch band, stainless steel and all-metal reeds and on how to centre the reed in the loom and to prevent "wash-boarding" of shuttles. C.

**Cotton Looms: Adaptation to Rayon Weaving.** H. E. Wenrich. *Textile World*, 1944, 94, No. 7, 56-57. Practical hints are given on the steps to be taken (overhauling, etc.) when a cotton warp has run out and is to be

replaced by rayon. It is recommended that particulars of the new cloth should be posted in the weaving shed a few days ahead of the time so that tacklers and others can collect any necessary accessories and plan their work. C.

**2×2-Twill: Weaving on Six Shafts.** H. R. Mauersberger. *Rayon Textile Monthly*, 1944, 25, 289. The writer reproduces two replies to a request for a chain pattern for a 2×2 twill on a 6-shaft taffeta weave, straight and skip enter. C.

**Weaving Shed Records: Application in Improving Efficiency.** A. R. Kandler. *Textile World*, 1944, 94, No. 6, 96-97. Suggestions are made for checking the efficiency of a tackler by making systematic records of smashes, new shuttles issued, cloth defects, pick counts and stoppages. Examples are shown. Different colours are used for recording different causes, e.g. smashes due to broken bobbins, broken shuttles or incomplete transfer of bobbins, might be recorded in black, red and green, respectively. C.

#### (D)—KNITTING

**Defective Knitted Fabrics: Description and Causes.** F. J. Quilitsch. *Textile World*, 1942, 92, No. 8, 77; No. 11, 122; 1943, 93, No. 12, 75; 1944, 94, No. 2, 121; No. 7, 95. The writer stresses the utility of a reference collection of defective materials and gives brief, illustrated descriptions, with suggested causes and remedies, of defects due to fuzzy needle lines, sinker lines, oil streaks, dropped stitches, knots in decorative and other yarns, and bad latches on the needles. C.

**Knitting Room: Humidification.** *Textile World*, 1944, 94, No. 6, 109-111. A simple statement is given of the advantages of humidification in knitting circular cotton hosiery. One recommendation is to aim at a regain of 8 per cent. in the yarn. Another suggestion is to maintain the knitting room at 72-78° F. and 55 per cent. R.H. C.

**Knitted Fabrics: Design.** J. C. H. Hurd. *J. Textile Inst.*, 1944, 35, P85-92. Types of ornamentation in knitted fabrics and garments are discussed. The term "design stitch unit" is introduced to represent the stitch or group of stitches forming a unit of the ground or the design effect in a patterned area, and examples of design stitch units and their combination in fabrics are considered. Mechanisms used for the selection of design instruments on knitting machines, including (1) spiral type pattern wheels, (2) multi-butt pressers, selectors or discs working on a depressing principle and (3) full Jacquard mechanisms, and examples of the types of designs obtained with them are discussed. C.

#### (G)—FABRICS

**Hand-loom Designs: Production on Power Looms.** F. W. Sterling. *Textile World*, 1942, 92, No. 8, 100. Illustrations are given of some decorative fabrics that were developed on a special hand-loom but could be woven on a dobby loom. C.

**Military Rayon Yarns and Fabrics: Adapting to Civilian Uses.** *Textile World*, 1944, 94, No. 6, 100-101. The writer discusses the prospects of the transition to civilian fabrics of (1) rayon cloths made specially for war and (2) cloths made from new types of yarn (strong viscose and acetate rayon, glass filament, nylon, Vinyon, etc.). Judged by current experience in the United States the transition should be smooth. C.

**Textile Designer: Function and Mill Organisation.** T. O. Ott. *Textile World*, 1943, 93, No. 9, 79-82; No. 10, 70-72; No. 11, 98-99; No. 12, 90-91. The writer discusses the place and functions of the fashion "stylist" and the designer who translates the stylist's ideas into fabrics. The first article deals with the inter-relations of the stylist, the sales organisation and the business and technical management. The second chapter is concerned with planning the designer's work and discusses his production of a point paper diagram and a weaving specification. Chapter III describes the planning of the manufacture of sample fabrics. Chapter IV deals with the costing of new fabrics. C.

**The Rag, Shoddy and Mungo Trade.** N. C. Gee. *Text. Mfr.*, 1942, 68, 240, 267, 330, 359, 399, 443, 479; 1943, 69, 32, 76, 121, 167, 227, 271, 302, 345, 395, 436, 482, 532; 1944, 70, 23, 67, 117. A series of illustrated articles dealing comprehensively with all aspects of rag treatment and shoddy and mungo produc-

tion. The collecting, sorting and blending of rags, and the carbonising and shaking, dusting and washing, drying, stripping and re-dyeing, blending and oiling, pulling, and cleaning and opening processes are described. Details are given of types of shoddy and mungo cloths, and the identification and assessment of raw material in rags. The articles conclude with a description of garnetting machinery, and with a list of terms and definitions. W.

**Printing Machine Blankets.** *Dyer*, 1944, 92, 177-181, 187. The qualities required in a printing machine blanket are listed, and the necessity stressed for a resilient and level foundation to obtain satisfactory impressions. Old (1850-1871) and recent patents dealing with washing apparatus and with various types of blanket fabrics are surveyed. Details are given of methods of waterproofing (including the use of blood albumen) and washing and cleansing. Precautions are necessary to avoid faults due to cold or damp blankets, to variations in tension and to creasing. W.

#### PATENTS

**Warping or Beaming Machines.** F. Lambach (Tenafly, New Jersey, U.S.A.). B.P.563,756/7/8 and 563,879/80/1/2/3 of 24/7/1942:1/9/1944 (Conv. 21/11/1941). (1) A warping or beaming machine equipped with an electromotor for causing a rotation of the warp beam is characterised in the arrangement of electrical means for the adjustment of a predetermined normal speed of the electromotor and in the arrangement of controlling means automatically controlled by a member held in contact with the winding on the beam for changing the speed of the electromotor from the normal value to a lower value in dependence on the building up of the winding on the beam. (2) The system comprising a motor circuit for connecting a source of current with an electromotor arranged for driving a beam includes automatic electrical controlling means responsive to the building up of the winding on the beam, which cause a variation of the operating speed of the electromotor by a variation of the electrical conditions of the system in such a manner that a substantially constant travelling speed of the warp yarns may be obtained. (3) Both the start switch and the stop switch of the electromotor may be actuated by the same movable controlling means, and selecting means are associated with the controlling means for selecting an actuation of either the start switch or the stop switch by the controlling means. (4) An electrical control system for the operation of braking means of a warping or beaming plant is characterised in that the system comprising a motor circuit for connecting a source of current with an electromotor arranged for driving a beam includes at least one circuit opening switch for causing an interruption of the motor circuit, that an electrical control responsive to an interruption of the motor circuit is arranged in the system for causing an actuation of the braking means upon such an interruption, and that the system includes a time relay responsive to an interruption of the motor circuit for causing at least a substantial release of the braking means after a period of time determined by the delaying action of the time relay. (5) A warping or beaming machine equipped with a drive for causing a rotation of a beam having a flange on each side of its ends and having a centre hole in each of its flanges is characterised in that the machine includes a driving head connected with the drive and arranged for driving engagement with one of the centre holes of the beam, and that an idling head arranged for engagement with the other centre hole of the beam is journaled in a bracket which is movable from an operative position with the idling head engaged with the centre hole of the beam into an inoperative position wherein the idling head is disengaged from the centre hole and the bracket permits free access to the flange of the beam. (6) The reed of a warping or beaming machine is movably arranged in the machine and automatic control means are associated with the reed for lifting it during the building up of the winding on the beam, the arrangement being such that, in operation, the warp remains in a substantially plane surface whereby any variable angles in the warp are avoided and the tension in the yarns remains substantially constant. (7) A beam support is provided which is swingably mounted on a stationary point of the machine and may be lifted by adjusting means from a lower beam receiving position, wherein the beam is disengaged from the drive, into an upper operative position, wherein the beam is coupled with the drive, and locking means are arranged for holding the support in the upper operative position. (8) A beaming or warping machine equipped with a drive for causing a rotation of a warp beam and with rotatable means rotated by engagement with the warp, is characterised

in that the machine comprises actuating means for a simultaneous actuation of a braking mechanism arresting the beam, and of braking means arresting the rotatable means, in combination with compensating means for compensating differences in the action of the braking mechanism and the braking means. C.

**Warping or Beaming Machine Storage Device.** F. Lambach (Tenafly, New Jersey, U.S.A.). B.P.563,855 of 24/7/1942:1/9/1944 (Conv. 21/11/1941). A storage device for a temporary unwinding of a portion of a warp from the beam comprises a pair of relatively movable gripping means which are normally in an inactive position permitting a free passage of the warp through the storage device. Driving means are connected with at least one of the gripping means for changing their relative position so as to cause the gripping of the warp. C.

**Circular Independent Needle Knitting Machine.** Wildt & Co. Ltd., H. H. Holmes and A. P. Saunders. B.P.563,905 of 5/1/1943:5/9/1944. In a modification of the machine described in B.P.545,676 there are provided a main knitting cam system for circular knitting only, including a stitch or knocking-over cam adapted to enable inactive needles to go through the system without reverting to the knocking-over position, an auxiliary knitting cam system for reciprocatory knitting, an additional series of butts associated with the needles intended to be active during reciprocatory knitting, and jacks adapted normally to position the additional butts for engagement with the auxiliary knitting cam system, the construction and arrangement being such that butts corresponding with jacks influenced by the narrowing picker or pickers are permitted to assume an inoperative position so as to avoid engagement with the auxiliary cam system and when the same jacks are influenced by the widening picker or pickers the corresponding additional butts are re-positioned for engagement with the system. In a machine employing ordinary needles the additional butts may be provided on the stems below the ordinary knitting butts, but in a machine of the characteristic type employing double-ended needles the additional butts are provided on the sliders engaged with the needles, e.g. below the transfer butts. C.

**Nylon Sizing Compound.** J. C. E. Bessieres and H. W. Best-Gordon. B.P. 564,027 of 6/11/1942:11/9/1944. A size for nylon and other yarns comprises casein or a compound thereof, e.g. an alkali caseinate, an oil, e.g. castor oil or arachis oil, in an emulsified or colloidal state, and an amide, e.g. urea. A sulphonated oil, preferably a sulphoricinate, or a sulphonated alcohol, preferably cetyl alcohol, and gelatin may also be added. The casein or casein compound (and gelatin) may be dissolved in an alkaline solution, e.g. in a dilute aqueous solution of ammonia, soda or borax. The size may be applied to yarn at normal room temperature during winding, warping or beaming operations, or to warp threads on the loom. C.

**Circular Knitting Machine.** Interwoven Stocking Co. (New Brunswick, New Jersey, U.S.A.). B.P.564,189 of 11/11/1942:18/9/1944 (Conv. 19/2/1942). The invention comprises a circular knitting machine having co-axial superposed needle cylinders and needles operable in either cylinder and transferable from one cylinder to the other by selectors associated with the needles and having selector butts engageable by selector levers which are movable into and out of operative position in predetermined order by a selector pattern drum to transfer selected needles, in which separate sets of selector levers are independently controlled to maintain one set of levers inoperative while levers of another set are moved into and out of operative position, and in which means are provided for orienting the selector pattern drum to the proper position for starting each of successive articles produced on the machine and for stopping the pattern drum at predetermined points during the knitting of each article to maintain the same needle selection for a number of courses. The invention further comprises a multi-feed circular knitting machine having coaxial superposed needle cylinders, needles operable in either cylinder, sliders for operating the needles in each cylinder and selectors associated with the needles and operable by selector levers to transfer selected needles from one cylinder to the other, in which means acting on the sliders are operable to by-pass selected needles at at least one of the feeds, and in which means are provided for independently controlling separate sets of selector levers to maintain one set of levers inoperative while levers of another set are moved into and out of operative position, selector levers of one set being actuated to produce Links-Links fabric, and selector levers of another

set being individually actuated to position alternate needles in the upper cylinder during the knitting of a number of courses, and thereafter to position selected needles in the upper and lower cylinders respectively to produce rib knit fabric other than  $1 \times 1$  rib for a number of successive courses. C.

**Insulating Fabrics: Production.** D. Finlayson and H. Crawshaw. B.P. 564,192 of 19/11/1942:18/9/1944. A fabric suitable for oiling or varnishing (e.g. for use as an electrical insulating fabric) comprises in both warp and weft, yarns of great tensile strength and low extensibility and yarns of relatively low strength and high extensibility woven together in such a way that the yarns of low extensibility are not interlaced with other yarns of the same kind but depend for their maintenance in the fabric structure on the presence of the yarns of high extensibility. When a fabric of this kind is treated with an insulating varnish it is found to possess a much higher resistance to tearing than a fabric of similar weight woven from the stronger yarns alone. It is particularly convenient to employ as the stronger yarn saponified cellulose acetate yarns that have been stretched. The yarns of lower strength may be cellulose acetate yarns or other thermoplastic yarns such as polyvinyl derivative yarns. Insulating varnishes, e.g. of the type comprising a basis of a drying oil, may be applied to the fabric by any suitable means. C.

**Cut Ribbons: Production.** C. Clay & Sons Ltd., C. R. Clay and Agnes M. Heasman. B.P.564,337 of 28/6/1943:22/9/1944. For the application of the method of B.P.544,379 to the cutting of a woven fabric, such as Petersham, consisting of cellulose acetate warp and relatively heavy cotton weft, the angle between the sides of the ridge on the periphery of the cutter disc is  $35-40^\circ$ , a radius of about 0.004 in. being formed at the edge of the ridge. C.

**Hosiery Tops: Knitting.** Hemphill Co. (U.S.A.). B.P.564,391 of 8/2/1943:26/9/1944 (Conv. 9/2/1942). A method of knitting with a machine having needles and sinkers includes feeding a yarn to all of a group of needles at one feeding station, feeding a second and relatively fine yarn at a second feeding station to alternate needles of said group leaving intervening or intermediate needles unsupplied with the second yarn, and causing the said alternate needles to draw the second yarn over the nibs of sinkers. A greater tension may be applied on the second yarn than on the first yarn. A rib-like fabric is produced by feeding a yarn to all the needles at one feeding station and feeding a second and relatively fine yarn to alternate needles at a second feeding station, and adjacent to the second feeding station causing alternate needles to draw the second yarn over the nibs of alternate sinkers only and knitting relatively tight stitches with the alternate needles and c.using each alternate needle in the knitting cycle to rob from the stitch drawn by the needle in advance thereof. C.

**Accordion or Mock Rib Fabric: Knitting.** Hemphill Co. (U.S.A.). B.P. 564,397 of 30/3/1943:26/9/1944 (Conv. 2/4/1942). A method of knitting an accordion type fabric wherein at one feeding station a yarn is knitted by all needles and at a second feeding station another yarn is knitted by spaced needles only and is floated over intermediate needles, is characterised by the step of elongating floats of the second yarn by robbing material for the floats from the stitches of that second yarn. Floats of the accordion yarn are elongated by extending them while robbing material from the adjacent stitches. Sinkers or web holders may be given an additional movement for the purpose of elongating the floats of the second or accordion yarn. The sinkers may be constructed with inclined nibs. A knitting machine for carrying out this method of knitting is provided with needles and sinkers which are independently controlled. Alternate sinkers may be provided with inclined nibs and intermediate sinkers constructed to have yarn drawn in their throats. C.

**Looped Fabric Articles: Production.** Elsa Horler (Barcelona, Spain). B.P. 564,413 of 8/9/1942:27/9/1944 (Conv. 9/9/1941). An article with strong loops resembling knitted loops is formed by the interlacement of horizontal rows of loops in such a way that each single loop is interlaced with loops of the neighbouring horizontal row and also with both of the lateral loops of the same horizontal row. The formation of the rows of interlaced loops may be carried out by using an embroidery machine and replacing the frame normally used for holding the base fabric by wire or string grating, the wires or strings of which can be withdrawn from the interlaced loops on completion of the articles. The grating may be rectangular for forming a fabric resembling

that knitted on straight-bar machines, or circular when fabric resembling fabric knitted on a circular machine is desired. In forming the fabric upon a rectangular grating it is advantageous to link the various loops in one row from right to left and in the next row from left to right, firm selvages being always formed in this way. In forming fabric resembling circular knitted fabric the interlacing of the horizontal rows of loops is effected in spiral form, so that in this way seamless stockings or other tubular goods can be manufactured. Fabrics resembling plain knitted fabrics in elasticity, softness, uniformity, fineness and transparency can be produced. C.

**Knitting Machine Yarn Changing and Splicing Mechanism.** H. H. Holmes, A. H. Widdowson and Wildt & Co. Ltd. B.P.564,510 of 4/1/1943:2/10/1944. Yarn changing and splicing mechanism comprises, in combination, a number of movable yarn guides, one or more for a striping yarn or yarns, respectively, others for a main or ground yarn, and a splicing yarn, respectively, and means for automatically operating the guides interchangeably so that a striping yarn is supplied to a section of the needles while the main or ground yarn and the splicing yarn are substituted for the striping yarn and supplied to the remainder of the needles during a course or a succession of courses of knitting, periodically, and in the intervals the main or ground yarn only is supplied to the said section of the needles and both the main or ground yarn and the splicing yarn are supplied to the remainder of the needles. A knitted fabric is produced wherein there are, coursewise, adjoining sections, one consisting of horizontal striping effects composed of the main or ground yarn only with which are interspersed partial courses of a striping yarn, or yarns, respectively, and the other consisting wholly of both main yarn and splicing yarn. The invention is applicable primarily to circular knitting machines, particularly to machines for knitting seamless hosiery. C.

**Nylon: Sizing.** Lister & Co. Ltd., W. Garner, F. G. Holroyd, Allied Colloids (Bradford) Ltd., G. Langley and R. Gill. B.P.564,737 of 28/12/1942:11/10/1944. Textile materials, composed of non-cellulose synthetic linear polymers such as nylon, in loose form, as a sliver, or as yarn, or in intermediate stages of processing or in other form are treated with a mixture of wax and oil in very fine aqueous dispersion with casein; after subjecting to customary textile operations such as setting, weaving or knitting, they may then be scoured. The combined percentage of wax and oil on the sized yarn may be between 0.5 per cent. and 10 per cent., and the percentage of casein between 0.5 per cent. and 5 per cent. The oil may consist of a light mineral oil and/or non-drying vegetable oil and/or a synthetic ester. The wax may be of hydrocarbon, vegetable or animal type. Antiseptics, emulsifying agents, anti-static compounds, fatty acids, colouring matter, antioxidants and insolubilising agents for the casein may also be included. If desired, petroleum jelly may be used alone instead of the mixture of oil and wax. A suitable scouring operation may consist of a treatment for 1 hour at 70° C. with 15 per cent. soap and 5 per cent. sodium carbonate, or alternatively 0.5 per cent. caustic soda, calculated on the weight of goods (liquor/material ratio 40:1). Woven or knitted fabrics may be set by steam blowing, decatizing or calendering after sizing but before scouring. Such pre-set material may be scoured and dyed in open width or rope form without the development of crease marks or other distortion of the fabric after drying. C.

#### 4—CHEMICAL AND FINISHING PROCESSES

##### (B)—BOILING, SCOURING, DEGUMMING AND WASHING

**Knit Rayon Outerwear Fabric: Processing.** E. S. Dunlap. *Textile World*, 1944, 94, No. 6, 121. Practical hints are given on the scouring, dyeing and scrooping of rayon outerwear fabrics. For scouring, a bath containing 2 per cent. of soda ash and 1 per cent. of a synthetic detergent is recommended; the cloth is treated on a reel for about 25 minutes at 180-190° F. If much oil is present, the addition of Na metaphosphate or pyrophosphate is advisable. Dyeing may be carried out in the same machine after rinsing. The "Tube-Tex" machine is recommended for scrooping and water-repellent finishes. C.

**Nylon Fabrics: Processing.** E. I. Du Pont de Nemours & Co. *Rayon Textile Monthly*, 1944, 25, 325-327. Practical advice is given on (1) scouring, (2) dyeing (and stripping), (3) finishing and setting, and (4) cleaning of nylon fabrics or garments. (See also Section 3A, above.) C.

**Jute Incrustants: Relation to Fibre and Yarn Strength.** B. P. Ridge, A. H. Little and J. Wharton. *J. Textile Inst.*, 1944, 35, T93-116. When jute is treated with the chemicals employed in textile purification and bleaching processes the lignin, hemicellulose and other incrusting substances are attacked and to some extent removed. Removal of substantially all the lignin with retention of hemicellulose, or of hemicellulose with retention of lignin, results in low wet strength although dry strength is but little affected. Treatments that result in the partial removal of both these incrustants usually reduce both dry and wet strength, although in hot alkaline steeps such as are given in peroxide bleaching, where fibre swelling can occur and there is no pronounced removal of incrustants, dry strength may be increased above the original value owing to the closer setting of fibre on fibre that occurs as a consequence of swelling and subsequent drying. Boiling under moderate pressure with sodium hydroxide solution removes substantially all the hemicellulose but little lignin, whilst treatment with acid chlorite solutions and then neutral sulphite liquor removes the lignin but not the hemicellulose. The incrustants in jute resemble in their behaviour the starch size on a low-twisted sized cotton yarn and whilst they themselves have little strength they contribute in marked manner to the strength of the jute by cementing together the ultimate cellulose fibre bundles on which the strength fundamentally depends. In oxidation treatments commonly employed in technical bleaching they appear to have a protective action on the cellulose. Alkaline hypochlorite has mainly an oxidising, and acid hypochlorite a chlorinating action on jute, and use of the latter in conjunction with pressure boil with sodium hydroxide and a final oxidation bleach with alkaline hypochlorite promotes attack and removal of lignin and fairly readily allows pure white cellulose to be isolated. If the preliminary chlorinating treatment is not given, more drastic boiling at high pressure is necessary and more than one boil may be required. The characteristics of the jute cellulose are such as to suggest that the product can be used satisfactorily for the manufacture of viscose, cellulose compounds and white papers. The "browning" of bleached jute that occurs when this material is exposed to sunlight can be prevented only when the conditions of purification are such as to ensure that no lignin remains, and it appears that lignin itself is the product responsible for the browning effect. C.

#### (E)—DRYING AND CONDITIONING

**"Dryair" Colloidal Silica Drying Elements.** R. K. Dundas Ltd. *Engineer*, 1944, 178, 271. A brief note is given about elements for (1) storing with goods to keep them dry, (2) keeping the interior of petrol engine cylinders dry, or (3) for protecting gun barrels, that use colloidal silica as desiccating agent. This may be tinted blue (with cobalt chloride) so that approaching exhaustion is revealed by a change of colour to pink. One element is effective for a year in an ordinary storage place and may be revived by heating at 200° C. for half an hour. C.

**Drying Cylinder Condensate High-pressure Return System: Advantages.** R. Lundrigan. *Textile World*, 1944, 94, No. 7, 70-71. Brief particulars are given of some American finishing works, in which the problem of providing steam for additional drying plant has been met by the installation of jet or centrifugal pumps and auxiliary gear for returning the condensate from the drying cylinders under high pressure to the boilers. With such plant it is possible to return the condensate from steam supplied at 100 lb. per sq. in. (338° F.) at 320° F., thus preventing the usual heavy heat loss if an open system is used to return water at about 210° F. C.

**Staple Fibre: Spontaneous Inflammability.** W. Specht. *Deut. Z. gerichtl. Med.*, 1942, 36, 174, 180 (through *Chem. Zentr.*, 1943, i, 801 and *Chem. Abstr.*, 1944, 38, 3483<sup>3</sup>). Staple fibre containing 140-200 per cent. water repeatedly gave rise to fires in the drying apparatus. The temperature of the steam-heated dryers was as high as 150°. The fires are attributed to some staple fibre that adhered to the dryer outside the actual oven space. Experiments showed that staple fibre which has charred is extremely autoxidisable. Such charred staple fibre can readily ignite spontaneously under the catalytic action of rust. The possibility of spontaneous ignition by electrostatic charges is considered. C.

**(G)—BLEACHING**

**Cotton Goods: Continuous Peroxide Bleaching.** D. J. Campbell. *Amer. Dyes. Rept.*, 1944, 33, 293-298. A continuous process for the bleaching of cotton goods consists of two basic steps each involving uniform impregnation of the cloth with its own weight of treating solution, heating to a predetermined reaction temperature in a chamber wherein the surfaces of the cloth are exposed to an atmosphere of conditioned steam, and storing or ageing the heated cloth without heat loss for a period of one hour. In the treatment of goods that do not contain dyed patterns, the first step is a treatment with caustic soda, usually a 3 per cent. solution. For fabrics containing dyed patterns the first step involves treatment with 0.5 to 1.0 (usually 0.5) volume hydrogen peroxide. For the second step a 0.5-1.0 volume peroxide bath is used. The temperature of the cloth during storage should be 205-210° F. The pH of the impregnation baths should be controlled in the range 10.4-10.8, using sodium silicate as stabilizing and buffering agent. Preliminary singeing, desizing and mercerising treatments may be incorporated in the process. Suitable impregnating apparatus and heating and storage chambers are briefly described. Operating speeds of up to 190 yards per minute have been reached. It is claimed that the steam consumption of this process is less than that of other bleaching processes, and that the total cost of chemicals used is lower than in any other method of peroxide bleaching and is well in line with the lowest figures for hypochlorite bleaching. C.

**Hydrogen Peroxide: Use as Antichlor.** B. Walther. *Wäscherci-Ber.*, 1942, 10, 67-71 (through *Chem. Zentr.*, 1943, i, 1013-1014 and *Chem. Abstr.*, 1944, 38, 3846<sup>n</sup>). Instead of sodium thiosulphate to counteract excess chlorine after bleaching, it is proposed to use hydrogen peroxide, which does not affect the copper washing drum and is more economical. Furthermore, the hydrogen peroxide has the advantage that on decomposition of chlorine lye, which often occurs, there remains a large excess of hydrogen peroxide after the antichlor action, and this acts as an after-bleach. Experiments with cotton and linen indicate that the fabrics are least affected by bleaching if hydrogen peroxide is used as antichlor. C.

**(H)—MERCERISING**

**Mercerisation: History.** W. Döhle. *Textilberichte*, 1943, 24, 430-434 (through *Chem. Abstr.*, 1944, 38, 3483<sup>2</sup>). A discussion of the discovery of mercerisation, chemical phenomena, theoretical basis, physical changes of the fibre, determination of the degree of mercerisation and future outlook. C.

**(I)—DYEING**

**Dead Cotton: Dyeing.** Marcel Pagerie. *Rayon Textile Monthly*, 1944, 25, 286. The author discusses the origin of dead cotton and its effects in dyeing. A recommended dyeing procedure for covering dead cotton is: Prepare the dye-bath with wetting agent as usual. Start dyeing at 120° F. with all the required dye present. Raise to the boil during the next half an hour and keep at the boil for another half an hour. Shut off the steam and add the required amount of salt. Allow to cool. Suitable dyes are mentioned. C.

**Vat Dye Oxidising Agents: Selection.** *Textile World*, 1944, 94, No. 6, 117. Recipes are given for vat dye oxidising baths containing (1) Na dichromate, (2) Na perborate, (3) hydrogen peroxide, (4) sodium chlorite and (5) ammonium persulphate. Nos. 1, 2, 3 and 5 are acidified with acetic acid and No. 4 has Na bicarbonate. No. 1 has the most rapid action and No. 5 the slowest; (1) is applied at 120-212° F., but (5) at 80° F. Formation of oxycellulose is deemed to be possible with all except No. 1 if control is not rigid. No. 1 can be varied over fairly wide ranges of temperature and concentration without much effect on the shade of the dyeing, but the other agents require closer control. All the agents give the same results with regard to the fastness of the dyeings, if properly applied. Dichromate is much more difficult than the other agents to rinse out of the cloth. C.

**Wollstra and Staple Fibre-Cotton Mixtures: Dyeing.** F. Richards. *Kunstseide u. Zellwolle*, 1942, 24, 614-616 (through *Chem. Zentr.*, 1943, i, 1220 and *Chem. Abstr.*, 1944, 38, 3479<sup>3</sup>). The treatment is similar to dyeing of part-woollen materials. Treatment before dyeing is accomplished in a hot bath with soap, Igepon T and Laventin KB. Size containing starch is treated with biolase,

Aktivin or similar product. In the presence of paraffin, montan wax or tallow, the size may be removed with Asordin. Substantive dyes are sufficient for most dyeing operations. For greater fastness Indanthrene or Naphthol-AS combinations may be employed. For light and medium tints many indigo salts may be applied by the slop-padding process, giving beautiful uniform shades. Para dyes developed with Nitrazol CF give good shades on cotton and viscose. For light tints it is best to use unmercerised cotton. Dyeing at various temperatures, with or without salt, is discussed. Indanthrene dyes are used on sensitive fabrics on the tension-free special jigger for rayon dyeing or drum. Improvement in uniformity of tint between cotton and rayon is obtained by slop-padding. Directions are given. Dyeing of dense fabrics is discussed. Naphthol AS-RR with mixtures of rayon and cotton penetrates deeper at higher temperatures than in the cold. C.

**Anthrasol Blue IBC: Piece Dyeing Difficulties.** W. Mitfessel. *Textilberichte*, 1942, 23, 492-493 (through *Brit. Chem. Physiol. Abstr.*, 1944, B II, 202-203). This dye is susceptible to oxidation and has a very low substantivity, particularly when used on spun rayon and delustrated rayon and in the presence of residual nitrous acid. A corrective is 1.5-5.0 g./l. of Dekol applied on the jigger and/or added to the dyeing or developing bath. Irregular dyeing, producing moiré effects, sometimes results especially in the presence of copper compounds. Peregol O is frequently a satisfactory corrective for this, but may fail if decorative effect threads dyed with an indanthrene dye are present. In such cases the most effective method is to ensure thorough and uniform penetration of the goods by the solution in the dye bath (special plant described). When dyeing foulards by the slop-pad method, high roll pressure and tensions should be avoided; the goods should hang as loosely as possible. C.

**Cellulose Fibres: Dyeing.** — Hajo. *Textilberichte*, 1943, 24, 511-513 (through *Brit. Chem. Physiol. Abstr.*, 1944, B II, 202). Factors affecting the uniformity of dyeing of cellulose fibres include variations in and too high a temperature in the dye bath, inadequate circulation of liquor in the bath, presence of fibre mixtures (e.g. under equal dyeing conditions Egyptian cotton acquires a stronger shade than American cotton), and inequalities produced in a pre-treatment process (e.g., bleaching, oiling, scouring, etc.) or in washing out the reagent after such treatment. In particular, hydrochloric acid formed from bleaching powder residues may attack the cellulose which then has a greater affinity for basic dyes and a lower affinity for direct dyes than has the normal fibre; oxycellulose behaves similarly. Mercerising may set up unequal tensions in the web which affect the uniformity of dyeing, and unequal distributions of dressings and of soap residues (e.g. precipitated by hard water or adsorbed on the fibre during too prolonged an interval between scouring and rinsing) act similarly. Imperfect fibres (e.g. "dead" cotton, or sulphur inclusions in viscose rayon) may produce patchy results, and a dyed cloth which appears satisfactory in one type of light may appear mottled in another. With cotton, the greater the fibre-dye affinity, the greater is the tendency to non-uniformity, and vice versa. C.

**Insoluble Azo Dyes: Fixation in a Single Operation.** A. Wolff. *Teintex*, 1942, 7, 247-255 (through *Chem. Zentr.*, 1943, i, 1418 and *Chem. Abstr.*, 1944, 38, 3844<sup>2</sup>). A discussion, based on patents, of (1) mixtures of naphthazoles with stabilized and passive water-soluble diazo components that liberate the active diazo compound on the fibre and can be coupled with naphthazole, (2) mixtures of naphthazoles and water-soluble fast bases which when treated with an acid liberate the base on the fibre (the bases are diazotised by sodium nitrite contained in the dye and couple with the naphthazole), (3) temporary solubilising of the dye and rendering it again insoluble on the fibre. C.

**Spun Rayon Fabrics: Dyeing.** L. Bonnet. *Monit. Maille*, 1942, 52, No. 734, 10-11 (through *Chem. Zentr.*, 1943, i, 1108 and *Chem. Abstr.*, 1944, 38, 3844<sup>1</sup>). The goods should be carefully cleaned by the use of Igepon, Igepal or fatty alcohol sulphonates, bleached with weak hypochlorite solutions or hydrogen peroxide, and dyed with Indigosols, Anthrasols or Hydron blue with the simultaneous use of the wetting agents Peregol OK or Igepon T. Piece goods are dyed best with vat dyes on the padding machine according to the pigment process. Sulphur dyes are employed either as Immedial-leuco dyes or with reduced Rongalite C. In all cases those dyes should be preferred which dye cotton and rayon staple equally well. C.

**Diphenylbenzene Derivative Substantive Azo Dyes: Production.** C. F. H. Allen and F. P. Pingert. *J. Org. Chem.*, 1944, 9, 50-54 (through *Brit. Chem. Physiol. Abstr.*, 1944, B II, 199). Technical *o*-diphenylbenzene is transformed into the 4:4'-diamino derivative, which after tetrazotisation couples very slowly with 2 mols. of a naphthol unless the solution is strongly alkaline, thus facilitating the isolation of monoazo dyes which do not colour cotton but dye wool from an acid bath. Addition of the tetrazo solution to a strongly alkaline solution of 2 mols. of H-acid yields a substantive dye. *m*-Di-*p*-nitrophenylbenzene is readily reduced ( $H_2$ , Raney Ni) to the diamino derivative, which gives a substantive dye when tetrazotised and coupled with H-acid. *p*-Di-*p*-nitrophenylbenzene is slowly reduced in dioxan at 110° and gives a substantive dye when tetrazotised and coupled with H-acid. It is suggested that a cross-conjugated system of multiple linkings and particle size contribute to substantivity. C.

**Indanthrone and Indigo: Structure.** R. Gill and H. I. Stonehill. *J. Soc. Dyers & Col.*, 1944, 60, 183-186. It is suggested that indigo, indanthrone, and certain of their derivatives are resonance hybrids of a number of contributing forms, as is generally the case with dyes, and that the resultant structure is a hydrogen-bonded type. Indications are given of the differences between this structure and the quinonoid polar form previously advanced and of the advantages offered by the former both from the viewpoint of theoretical organic chemistry and in the interpretation of (1) the colour of indigo in various solvents, (2) the lack of pronounced colour change in the normal vatting of indanthrone and some of its derivatives, (3) the necessity for the reduction of only two of the four quinonoid oxygen atoms in the normal vatting of indanthrone, (4) the absence of semiquinone formation in indanthrone, (5) abnormally large differences between the standard redox potentials of the first and second leuco-compounds of indanthrone, and (6) the differences between indanthrone and its N-methyl derivative. C.

**Dyed Canvas: Resistance to Atmospheric Conditions.** F. I. Sadov. *Tekstil. Prom.*, 1944, 4, No. 1, 15-17 (through *Chem. Abstr.*, 1944, 38, 3845<sup>5</sup>). Various treated samples of canvas were tested for resistance to light, to cold water, to washing in hot water, to perspiration, to rubbing and to atmospheric conditions. Insolation destroys cotton web rapidly. A fabric prepared for dyeing (sized and washed) lost 37.5 per cent. of its strength in 2 months and 41 per cent. in 4 months exposure. Fabrics dyed with direct dyes were somewhat more resistant to insolation than undyed fabrics. After-treatment with metal salts considerably increases this resistance. After-treatment with copper and chromium salts or with copper sulphate alone, greatly improves the light fastness as well as other properties of fabrics dyed with direct dyes. After-treatment with a waterproofing emulsion and aluminium acetate did not affect any of the other properties. Best results were obtained with a specimen dyed with (for 142 kg. of fabric): Direct Brown K 150, Direct Blue K 280, Direct Yellow Z 1440, sodium chloride 4000, sodium phosphate 2000 g. and water 200 l. After dyeing, the fabric was treated at 95-98° in potassium dichromate 2200, copper sulphate 2000 g., acetic acid (30 per cent.) 3 and water 150 l. After washing, the fabric was waterproofed and treated with a solution of aluminium acetate. C.

**Dyed Cotton: Light Fastness; Effect of pH.** C. A. Seibert and C. A. Sylvester. *Amer. Dyes. Rept.*, 1944, 33, 311-312. Tests were made on samples of cotton cloth which had been dyed with various types of dyes by the usual methods and given neutral, mild acid and mild alkaline finishing treatments. It was found that the light fastness of samples dyed with many direct, developed and sulphur dyes was definitely inferior when the cloth pH was 3.5 compared with the fastness at a cloth pH of about 7. Cotton coloured with azoic and vat dyes exhibited only minor differences under these conditions. At a pH between 8.5 and 9.5 the fastness of cotton dyed with direct and developed dyes was slightly superior or slightly inferior to that at or below pH 7 according to the particular dye used. With variations in pH between 7 and 9.5, cotton dyed with azoic and sulphur dyes exhibited only minor differences in light fastness, except in the case of sulphur blacks which were consistently superior at the higher pH values. At the higher pH values, cotton dyed with vat dyes was outstandingly inferior to the cotton at or below pH 7. Retention by vat dyed cloth of a small quantity of a mildly alkaline soap was sufficient to

reduce appreciably the light fastness of some of the dyes. Improvements could be effected, even after storing for some time, by rinsing in water containing a small quantity of acetic acid. A few experiments indicated that the presence of 0.5 per cent. of sodium chloride or acetate in the cloth did not influence the light fastness of the vat dyes. A convenient method for the determination of the pH of cloth is described and data are given showing the pH values of vat dyed cloth after rinsing, soap and other treatments. C.

**Vat Dyes and their Uses.** E. Greenhalgh. *Canadian Text. J.*, 1944, 61, No. 14, 35-36, No. 16, 38, 51. After a brief survey of the historical development of the vat colours, the constitution and characteristics are described of the indigoid and Indanthrene types, and details given of their application to fabrics and yarns, including a note on the pigment padding process. Stress is laid on the valuable fastness properties of the vat dyes. W.

**Theory of Dyeing. XII. Absorption by Wool of Acid Dyes with Different Numbers of Sulpho Groups.** A. E. Porai-Koshits, E. A. Veller and N. V. Sokolova. *J. Appl. Chem. (U.S.S.R.)*, 1943, 16, 28-35 (English summary) (through *Chem. Abs.*, 1944, 38, 3131). Three dyes (Acid Red Zh, Acid Red S and Acid Orange Light-stable) of similar structure, but varying in number and positions of the acid groups, were studied in respect to absorption on wool. Dyed in presence of sulphuric acid at pH 2.2-5, the same saturation limit of 0.8 mg. equivs. per g. was found as in previous work (these *Abs.*, 1940, A495) as the maximum amount of acid dyes chemically absorbable by wool. At pH 1.5, or less, a slight increase of absorption was found which may be due to partial hydrolysis of wool keratins. Greater absorption was noted for wool washed by organic solvents than for that washed only with ammonium carbonate. Dyeing in presence of hydrochloric acid showed somewhat higher absorption than in presence of sulphuric acid. W.

#### (J)—PRINTING

**Luminescent Pigments: Application.** *Textile World*, 1944, 94, No. 6, 91. Hints are given of the possible uses of fluorescent and phosphorescent pigments, in suitable vehicles, for decorating textiles. These materials are now produced by the ton at about 0.90-2.50 dollars per lb., but more than 90 per cent. of the output is consumed for non-textile, military purposes. The fluorescent pigments are based on Zn and Cd sulphides, and the phosphorescent ones on crystalline forms of Zn, Cd, Sr and Ca sulphides. Suitable vehicles are methacrylate and vinyl plastics. C.

**Luminescent Pigments: Application in Textiles.** M. A. Heikkilä. *Rayon Textile Monthly*, 1944, 25, 296, 345. A brief review is given of fluorescent and phosphorescent pigments and their probable post-war applications in coated and printed fabrics. A present major application is in phosphorescent adhesive tape which is used in all ships of 3,000 tons or more to supply directional markings in the event of power failure. C.

**Rayon Velvet: Printing.** *Rayon Textile Monthly*, 1944, 25, 294-295. Practical hints are given on the preparation for and printing of rayon velvets, especially those with cellulose acetate pile. C.

**Cellulose Fabrics: Printing.** A. Wolff. *Teintex*, 1942, 7, 284-285 (through *Chem. Zentr.*, 1943, 1, 1108 and *Chem. Abstr.*, 1944, 38, 3845<sup>b</sup>). The use of the following is discussed: Indigosols and Rapidogens, insoluble azo dyes that can be developed and fixed with and without acid (Rapidogens, Rapid fast dyes and Rapidazols), and water-soluble dyes that are made insoluble in the fibre (Neocoton dyes, pigment dyes like Aridyces and Impralac). C.

**Lining Fabrics: Printing.** *Textile Recorder*, 1944, 62, September, 63-67. A general description of singeing, bleaching, dyeing, printing and finishing for the production of lining fabrics. C.

**Rayon Fabrics: Printing.** T. Fischer. *Textilberichte*, 1942, 23, 493-495 (through *Brit. Chem. Physiol. Abstr.*, 1944, B II, 203). Special problems arising in the printing of rayon as distinct from cotton and spun rayon products are dealt with by the new types of German machines described. Pre-treatment is important (e.g. with lactic acid or glycerol); Ramasit in particular makes the web slightly water-repellent and gives very sharp printing effects. Glazing between rollers is also effective, but is apt to damage rayon goods if overdone. Synthetic rubber printing rollers have given excellent results. Paste formulae

recommended contain Anthrasol Blue IBC 15, in the presence of sodium chlorate 2, tragacanth-starch 200, and ammonium metavanadate about 55 g./l.; or Rapidogen Blue B 15, in the presence of urea 25, caustic soda lye 25, ethyl alcohol 25 and tragacanth-starch 200 g./l. A 15-20 per cent. increase in production is obtainable by the use of the automatic paste feed described. The solution is contained in a closed airtight reservoir, and the outlet from a pipe in the bottom dips below the level of the solution in the feeding trough; the latter level is thus automatically maintained constant. C.

#### (K)—FINISHING

**Plastic Coating Applying Machines: Types and Limitations.** J. B. Cleaveland. *Textile World*, 1944, 94, No. 3, 74-76; No. 5, 90-91; No. 6, 107, 111; No. 7, 81-85. An illustrated description is given of knife coating, knife spreading, knife blanket, knife roller, reverse roller, extrusion and spraying types of machines for applying plastic coatings and precautions to be observed when using them are discussed. C.

**Superheated Water Systems: Application in Finishing Plant.** P. L. Geiringer. *Textile World*, 1944, 94, No. 6, 104-105. The author stresses the advantages of heating by superheated water, conveyed in relatively narrow pipes, for various operations in dyeing, printing, finishing, humidification, etc. Even the steam cylinders of a drying machine can be conveniently supplied from a local steam-raising unit fed by the superheated water. It is economical to set the boiler plant for about 400 lb. per sq. in. pressure, and 75-80 lb. back-pressure, thus providing water at 310° F. or more. C.

**Cerex Resins: Properties and Uses.** C. L. Jones. *Modern Plastics*, 1944, 21, No. 11, 83-84, 166, 168. The causes of the poor dimensional stability of thermoplastic resins are discussed and the advantages of Cerex resins are pointed out. The Cerex resins have heat distortion points (American Society for Testing Materials) ranging from 195 to 300° F., values that actually overlap similar figures for many thermosetting moulding compounds. Early developmental work has been confined to the X-214 brand which has a heat distortion point of approximately 225° F. Tables are given showing the thermal, mechanical and electrical characteristics of this resin and of polystyrene, and the results of treatment for 48 hours with boiling water of compression-moulded disks of general-purpose phenolic and urea resins, and Cerex formulation X-214. The mechanical properties of the Cerex resin are fully equivalent, if not superior, to those of polystyrene, and the dielectric strength is superior to those of the electrical grades of phenolic moulding compounds. The A.S.T.M. arc resistance is similar to that of polystyrene, in the neighbourhood of 70 sec. This new resin retains the chemical resistance of polystyrene, and moulded parts can be boiled in battery acid for a sustained period with no appreciable effect. It is soluble in aromatic and chlorinated hydrocarbons but insoluble in aliphatic hydrocarbons. War-time applications and projected post-war uses are indicated. Moulding of Cerex resins is briefly discussed. C.

**Softening Agents: Effect on Fabrics.** S. Ueno. *J. Soc. Chem. Ind. Japan*, 1941, 44, Suppl. Binding 101-103 (through *Chem. Zentr.*, 1943, i, 1016 and *Chem. Abstr.*, 1944, 38, 3482<sup>n</sup>). Lauric, myristic, palmitic, stearic and oleic acids and paraffins produced a stiffening instead of a softening effect. Peanut oil, fat acid esters, cholesterol, turpentine, eugenol, menthol, etc., showed slight softening effects. An excellent softener is cetyl ethyl ether, prepared from cetyl iodide and sodium ethylate. C.

**Starch Finishes: Characteristics.** *Rayon Textile Monthly*, 1944, 25, 291-293. A broad review is given of the colloid properties of the common starches (gelatinization, retrogradation, viscosity, effects of salts) that govern their behaviour in finishing. C.

**Cotton Fabrics: Shrink Finishing.** F. R. Redman. *Textile World*, 1944, 94, No. 7, 91. A brief report is given about a shrink-proofing process in which the cloth is advanced along a conveyor in a rumpled, loose manner, is exposed to steam spray, and finally dried. Reports of laundering tests on knit cotton under-shirts are recorded. The unfinished cloth shrank about 14 per cent. in one wash and nearly 20 per cent. in 20 washes, but the values for the finished cloth were 3.4 and 6.5 per cent. The finished cloth reached fairly constant

dimensions after very few washes. The U.S. Underwear Institute has appointed a committee to investigate the machine. C.

**Gelatin: Use in Finishing.** H. J. Henk. *Gelatine, Leim, Klebstoffe*, 1942, 10, 127-129 (through *Chem. Zentr.*, 1943, i, 1836 and *Chem. Abstr.*, 1944, 38, 3846<sup>5</sup>). A discussion of the use of gelatin as protective colloid in boiling out cotton, as dispersing agent for lime soap, as stabilizer for olein emulsifying agents and for hydrogen peroxide baths, as dyeing assistant, as reserve assistant for indigosols, as sizing medium, and for protecting wool during chlorination and against proteolytic damage. C.

**Seaweed Powder: Use for Sizing.** P. Islent'ev. *Tekstil. Prom.*, 1944, 4, No. 2/3, 15-18 (through *Chem. Abstr.*, 1944, 38, 3846<sup>6</sup>). Sodium alginate is suitable for sizing and finishing textiles and as a thickener for basic dyes. Because the cost of extraction is high, experiments were made on the use of finely ground, whole seaweed, containing moisture 13.8, ash 27.4, water-insolubles at 40° 56.9 per cent.; the insoluble matter includes 26.8 per cent. of alginic acid. Details are given of a method of determining alginic acid. Na, K, NH<sub>4</sub>, Li and Mg alginate solutions are 10-12 times more viscous than similar concentrations of starch. Size is best prepared from powdered seaweed not less than 4 per cent., and sodium carbonate 20 per cent. of the weight of air-dry powder, by heating at 60-65° for 45-60 min. For sizing textiles powdered seaweed can be used alone or mixed with corn, wheat or rye flour. C.

**Starch: Chemistry and Application.** *Textile Recorder*, 1944, 61, Jan., 65-67, 56. In continuation of previous articles, the writer describes the processes of starch mangling, back-filling and drying, with particular reference to recipes and machines. C.

**Oilcloth: Development.** F. J. Tuttle. *Textile Research*, 1944, 14, 228-232. A review of the development of oilcloth, including oiled silk, cotton and other fabrics, tarpaulins, floor coverings and American or leather cloth. C.

**Complex Organic Compounds in the Textile Industry.** *Dyer*, 1943, 90, 127-128, 167-169, 201-203, 247-251, 277-279, 317-318, 359-360, 401-403, 441-443, 481-484; 1944, 91, 15-16, 97-99, 183-185, 202. The constitution, textile uses and evaluation are described of soaps (including those for special purposes, e.g. wool scouring and milling soaps, and solvent, ethanalamine and glycol soaps), non-detergent soaps (e.g. aluminium soaps for waterproofing, copper soaps for rotproofing and other metallic soaps for various purposes), sulphonated oils and sulphonated fatty alcohols, surface-active agents, quaternary ammonium compounds, dye levelling agents and emulsifying agents. The textile uses are also given of glue, casein, lecithin and other protein auxiliaries. The characteristics of certain surface-active agents and the constitution of wetting agents are discussed in detail. W.

#### (L)—PROOFING

**Textile Materials: Waterproofing.** E. Dutoit. *Teintex*, 1942, 7, 82-84 (through *Chem. Zentr.*, 1943, i, 1016 and *Chem. Abstr.*, 1944, 38, 3483<sup>4</sup>). The material is impregnated at pH approximately 4.5 with a solution of animal or vegetable albumin, fixed by steaming or by brief treatment with hot water, and soaped hot at pH 7.5. The soap bath can be replaced by an emulsion of a higher fat acid; a mixture of oleic and stearic acids is most suitable. It is advantageous to add some wax to the fat acid emulsion. C.

**Fabrics: Waterproofing.** L. Bonnet. *Teintex*, 1942, 7, 285-290 (through *Chem. Zentr.*, 1943, i, 1433 and *Chem. Abstr.*, 1944, 38, 3847<sup>2</sup>). A general discussion of the porous waterproofing finish of textiles. Protective layers on fibres are produced by double-bath treatments with aluminium acetate and soap or with alkaline alginates and by various single-bath treatments. The following new commercial products are discussed: Tylose, Apermene N (Francolor), Ramasit I and K conc. (I. G.), Praedigen T (Roehme), and Waxol (I.C.I.). The fibre can be waterproofed by changing its surface, as by esterification and etherification. Applications of Velan PF and of Persistol (I. G.) are described. C.

**Ferrous Sulphate: Use in Waterproofing.** O. A. Samsonova. *Tekstil. Prom.*, 1944, 4, No. 1, 20-21 (through *Chem. Abstr.*, 1944, 38, 3846<sup>6</sup>). Waterproofing with ferrous sulphate requires an oxidation treatment. Oxidation has the disadvantage of causing a yellowing of the fabric, but it increases water resistance

and fastness to sunlight. Oxidation is best effected in a solution of potassium dichromate. If pure ferrous sulphate is used, the solution of dichromate is acidified with acetic acid. If the ferrous sulphate contains any ferric iron, sulphuric acid should be used in the oxidising solution. In this case the fabric must be thoroughly neutralised. Details of the process are given. C.

**Mercury: Determination in Mildew-proofed Textiles.** D. A. Shiraeff. *Amer. Dyes. Rept.*, 1944, 33, 310 and 315. For the determination of mercury in textile materials which have been mildew-proofed with organo-mercuric compounds, a sample (0.25 g.), shredded or cut into small pieces, is left in 20 c.c. of ether saturated with hydrochloric acid for 20-30 min. with occasional shaking, the ether is evaporated and 5 c.c. of chloroform and 10 c.c. of distilled water are added. The mixture is then titrated with a solution of dithizone in chloroform until the colour of the chloroform layer changes from orange to a slightly greenish dark brown. The dithizone solution is standardised by a similar titration with a mercuric chloride solution of known composition. The method is reliable and rapid. C.

#### PATENTS

**Polyvinyl Esters: Saponification.** R. P. Roberts, E. B. Johnson and H. H. Taylor. B.P.563,991 of 21/11/1941:7/9/1944. A process for the production of polyvinyl compounds containing hydroxyl groups comprises saponifying a polyvinyl ester in a solution consisting of an alkali, a lower aliphatic alcohol, and water in amount 1-10 per cent. of the total weight of liquid, the amount of alkali being substantially less than is equivalent to the ester group to be displaced. Products in which the final proportion of hydroxyl group to ester group is such as to impart to the compound a degree of solubility in water are particularly valuable for the manufacture of yarns, fabrics, etc., which are soluble or dispersible in water. For this purpose the amount of water in the saponification medium should be such as to give an ester content of 30 per cent. or lower, and preferably between 2 and 12 per cent. C.

**Tetrakisazo Dyes: Production.** Society of Chemical Industry in Basle. B.I.P. 564,024 of 2/9/1942:11/9/1944 (Conv. 2/9/1941 and 17/7/1942). Tetra-kisazo dyes are made by tetrazotising and coupling with 2 molecules of 1:3-dihydroxybenzene or 1-amino-3-hydroxybenzene, a diaminodisazo dye of given general formula. The diamino compound is advantageously prepared by coupling in an alkaline medium a diazo compound of the benzene or naphthalene series which contains in meta- or para-position to the diazo group a group capable of conversion into an amino group, e.g. a nitro group or an acidylamino group, and may also contain other substituents, with an amino-naphthalenesulphonic acid of given general formula, diazotising the resulting monoazo dye, coupling it with a so-called middle component of the naphthalene series and finally converting into an amino group the group in the initial component capable of such conversion. The tetrakisazo dyes have a pronounced affinity for natural and regenerated cellulose fibres. The shades obtained vary from red-violet to grey-violet, dark brown and olive green. The shades are not substantially altered by after-treatment with formaldehyde, but may be altered to a greater extent when developed with diazotised *p*-nitraniline. C.

**Shock-absorbing or Cushioning Material: Production.** Lister and Co. Ltd. and W. Garner. B.P.564,026 of 2/11/1942:11/9/1944. A shock-absorbing or cushioning material comprises three or more textile fabrics held or secured in superposition and at least two layers of resiliently flexible elements respectively connecting adjacent fabrics by being woven into one of the latter and by being secured by adhesive to the other, these resiliently flexible elements providing "legs" between the adjacent fabrics which, due to their length, their substantial inclination, or approach to normality, to the surfaces of the fabrics and their resistance to collapse, are capable of holding the fabrics spaced apart at least 0.1 in. or, if external compression has been applied, of restoring them to such spacing apart when the compression is released. The material may be produced by securing together two or more pile fabrics by adhesive between the tips of the pile on one fabric and the backing of the next fibre. Alternatively two or more double pile fabrics may be superposed with the interposition of a layer of cloth secured by adhesive to the pile contiguous to it on both sides. A layer of cloth is secured by adhesive to the exposed pile or piles of the outer fabric or fabrics of the composite structure. The resilient connecting elements may be dis-

posed in groups or strips separated by gaps and a honeycomb structure may be produced. With mohair yarn connecting elements satisfactory results may be obtained with "leg" densities between 250 and 2,000 per square inch, and fabric spacings of 0.1 to 0.4 in. Materials made from various other types of fibres, e.g. wool, cotton, rayon, kapok, glass and asbestos, may be used. C.

**Plastic Bead Decorated Fabrics: Production.** H. Freiberg. B.P.564,104 of 12/2/1943:13/9/1944. A process for the decoration of a fabric to simulate beadwork comprises applying a mixture of a heat-hardenable urea-formaldehyde resin, a hardener and, if desired, a pigment, the mixture being extruded in single drops on to the surface, and heating the material in an oven to about 120° F. so as to convert the composition to the hardened and insoluble condition. C.

**Differentially Dyed Fabrics: Production.** Courtaulds Ltd., C. M. Whittaker, H. A. Thomas, C. C. Wilcock and C. P. Tattersfield. B.P.564,131 of 10/3/1943:14/9/1944. A process for the production of differential dyeing effects comprises impregnating the fabric with a solution or suspension of a non-volatile dye or of resin-forming compounds which are capable of altering the dyeing properties of the material of the fabric, and evaporating the liquid more rapidly from one portion of the fabric than elsewhere. With a dye, the two portions of the fabric are thereby differently coloured, and with resin-forming compounds, different colour effects are obtained on subsequently heating the fabric to effect condensation and then dyeing. If hot or cold air is blown on to one side of the impregnated fabric the two sides will or can be differently coloured. For the production of a differential effect on one side of the fabric, stencils, templates or other suitable means may be used for localising the evaporation. The resin-forming compounds may be cyanamide and formaldehyde, and the impregnating liquid may also contain an intensifier such as ammonium thiocyanate. C.

**Tetrakisazo Dyes: Production.** Society of Chemical Industry in Basle. B.P.564,258 of 2/9/1942:20/9/1944. Tetrakisazo dyes are made by tetrazotising a diamino-disazo dye of given general formula and coupling the tetrazotised dye with 2 mols of resorcinol or with 2 mols of 1-amino-3-hydroxybenzene. The parent diaminodisazo dye may advantageously be made by combining a diazotised aminoazo dye of the general formula  $t \cdot R_1N:N \cdot R_2 \cdot NH_2$ , in which  $t$  stands for a nitro group or an acidylamino group, in an alkaline medium with an aminohydroxynaphthalene sulphonic acid, and then converting the nitro group or acidyl amino group in the resulting dye into an amino group by reduction or saponification. The tetrakisazo dyes have a pronounced affinity for natural and regenerated cellulose fibres. The shades obtained vary from red or red-violet to dark blue-green, olive green, black and brown. The shades are not substantially altered by after-treatment with formaldehyde, but may be altered to a greater extent by development with diazotised *p*-nitraniline. C.

**Textile Fabric Petrol Tanks: Production.** Courtaulds Ltd., C. Diamond and A. Hill. B.P.564,265 of 4/1/1943:20/9/1944. Receptacles for organic liquids, and in particular petrol tanks, can be manufactured by completely forming the receptacle from a composition consisting of a cellulose ester, e.g. cellulose acetate, together with a plasticiser, and then saponifying the inside surface of the receptacle to such a degree that the walls of the receptacle are capable both of resisting swelling and also removal of the plasticiser therefrom when in contact with the organic liquid. The cellulose ester sheet may have a backing of fabric, e.g. of cotton, rayon, or wire, and/or may be surrounded with self-sealing layers of bullet-proofing materials. C.

**Wetting Agent: Preparation.** A. E. Everest, J. A. Wallwork and M. Briscoe. B.P.564,359 of 18/1/1943:25/9/1944. A wetting agent, which is a clear liquid miscible with mineral oils, is prepared by treating a mixture of one or more cyclo-aliphatic amine salts of sulphonated or sulphated aliphatic primary, secondary or tertiary alcohols containing at least 8C atoms, the corresponding cyclo-aliphatic amine sulphate, and one or more organic solvents in which the salts are soluble, with an inorganic salt, e.g. common salt, if necessary with the addition of water, and separating the clear oily layer. The salts are preferably the cyclo-aliphatic amine salts of sulphonated or sulphated lauryl alcohol. Such compositions are suitable for use either as such or when mixed with a mineral or coal tar oil for wetting out and penetrating with oil materials

saturated with water, such as wet paper, leather, textile fibres, pigments, lakes, mineral and vegetable matter, and increasing the spreading power of oil on water or wet surfaces. C.

**Laminated Fabric: Production.** British Celanese Ltd. B.P.564,364 of 24/2/1943:25/9/1944 (Conv. 25/2/1942). In a laminated fabric comprising an assembly of three fabric layers bonded together face to face by means of a thermoplastic film-forming material contained in at least one of them, the inner layer of the assembly is a thermoplastic fabric coated on one face with a thermoplastic film and both outer fabric layers of the assembly have a water-repellent coating. Preferably, the two outer fabric layers are provided by a single sheet of fabric folded to enclose the inner layer of fabric. Preferably, the outer fabric is made wholly or in part of yarns of a thermoplastic material such as cellulose acetate or other organic derivative of cellulose. Laminated fabrics of the type described are suitable for sweat-bands for hats. C.

**Factice and Gelled Rape Oil: Application in Waterproofing.** Ioco Rubber & Waterproofing Co. Ltd., A. Ryan and G. Cameron. B.P.564,422 of 1/3/1943:27/9/1944. A method of waterproofing fabrics comprises applying thereto a composition consisting essentially of a mixture of gelled rape oil and white factice, and hot curing. The method is equally applicable to the production of single-proof or double-proof fabrics. The fabric may be given a preliminary coating to promote adhesion of the main coat and to prevent "striking" through open texture fabrics. A sticking coat may be applied to promote adhesion when the fabric is doubled in the production of double-proof fabrics. For single-proof fabrics, the sticking coat is omitted and the fabric given any desired surface finishing treatment. The main coat is preferably prepared from a mixture of gelled rape oil, white factice, stearine pitch, whiting, zinc oxide, sulphur and an accelerator (tetra-ethylthiuram disulphide), the mixture being worked into spreading consistency with naphtha. The preliminary coat is preferably prepared from a mixture of gelled rape oil, white factice, zinc oxide, sulphur and accelerator, the mixture being worked into spreading consistency with naphtha. The sticking coat is preferably prepared from a mixture of gelled rape oil, dark factice, stearine pitch, bitumen "A" (asphaltic bitumen), china clay, vegetable black, zinc oxide, sulphur, accelerator (zinc iso-propyl xanthate) and stearic acid, the mixture being worked into spreading consistency with naphtha. C.

**Printing Blanket Washing Apparatus.** A. Abbey (Dewey and Almy Chemical Co., Cambridge, U.S.A.). B.P.564,565 of 28/7/1943:3/10/1944. A process of removing colour from the surface of a textile printing blanket in a printing machine having two blanket washing stations separated by the outward run of the blanket includes the steps of mechanically transferring a part of the soft colour to a metallic surface, breaking up the film of colour adhering to the blanket by wet-brushing the film, flooding the remaining colour with a swelling agent and diluent, maintaining the diluent in contact with the colour and blanket during the outward run of the blanket, and finally removing both diluent and colour from the blanket before it is dried. The machine is provided with blanket washing and colour diluting means located adjacent to the printing machine comprising a colour transfer roll which contacts with and removes colour from the blanket surface, means for removing colour from the transfer roll, brushing means capable of scrubbing the blanket surface, and means for supplying and maintaining a sheet of water on the blanket during its outward run to the second washing station. C.

**Printing Backing Surface Protective Coating: Application.** A. Abbey (Dewey and Almy Chemical Co., Cambridge, U.S.A.). B.P.564,566 of 28/7/1943:3/10/1944. In a backing-surface printing process for printing on fabric, porous paper or other porous web, there is applied to the supporting surface (impression surface), which may be a flexible blanket or draw sheet, a temporary continuous coating which receives the surplus ink passing through the fabric or porous web, and which coating is removed periodically and immediately replaced by a fresh coating. Ordinarily, but not necessarily, the coating is replaced after each impression. The coating composition is a material which can be applied in liquid or plastic form to the supporting surface, which will dry or harden quickly, and which will form a continuous surface so that surplus ink will not penetrate to the supporting surface and which material can

be removed easily after printing. The coating composition may, for example, be an aqueous suspension of bentonite and a rubber-loading or paper coating clay, or a mixture of ammonium alginate, whiting and water. C.

**Textile Materials: Fire-proofing.** Geigy Colour Co. Ltd. and C. Hobday. B.P.564,573 of 13/8/1942:4/10/1944. Flame-damping and fire-proof properties are imparted to textile materials by treating them with a solution of a water-insoluble condensation product made by reacting, in the presence of an alcohol, a nitrogen compound containing a five- or six-membered heterocyclic ring in which the grouping  $-N:C.NHX$  (where X is H or  $NH_2$  and the atoms connected by the double bond form part of the heterocyclic ring) is present at least twice with an aldehyde, especially formaldehyde, or a substance liberating an aldehyde, and containing at least an equal weight of non-inflammable plasticizer and then heating. The material may be treated by dipping, steeping, soaking or padding and may afterwards be squeezed and dried before heating. The water-insoluble condensation product may be one obtained by heating melamine or a guanazole with formaldehyde or with a substance yielding formaldehyde in ethyl alcohol. Other five-membered or six-membered heterocyclic nitrogen-containing compounds of the character indicated, such as cyanuric trihydrazide, may be used. Suitable non-inflammable plasticizers are organic esters of phosphoric acid, especially chlorinated alkyl esters of phosphoric acid. The final properties of the materials can be varied by varying the relative proportions of the components and/or the duration and temperature of the heating treatment. The fire-proofing and fire-proof properties show a high standard of resistance to water. C.

**Cellulose Materials: Parchmentisation and Vulcanisation.** Tootal Broadhurst Lee Co. Ltd. and W. H. Roscoe. B.P.564,583 of 10/12/1942:4/10/1944. Cellulose materials, such as fibres, yarns, films, sheets, scoured sawdust, wood pulp or macerated paper are treated with sulphuric acid of parchmentising strength without substantial solution of the cellulose after a preparatory treatment with sulphuric acid of less than parchmentising strength. By subsequent pressing and drying the treated materials may be formed into a homogeneous mass valuable for its hardness, lightness and electrical insulation properties, and capable of being moulded under heat and pressure. C.

## 5—ANALYSIS, TESTING, GRADING AND DEFECTS

### (A)—FIBRES

**Cotton Fibre: Spinning Quality Tests.** A. C. Walters. *Textile World*, 1944, 94, No. 7, 58-59, 164-166. A brief review of American methods of testing cotton staple (Suter-Webb duplex sorter, Hertel fibrograph), fibre strength (Pressley and Chandler methods), fineness (weight per unit length), cross-sections and convolutions (microscope) and alignment of micelles (X-ray angle). C.

**Fibres: Molecular Structure.** C. S. Venable. *Textile Research*, 1944, 14, 179-182. The molecular structures of silk, wool, nylon, Vinyon, cellulose and cellulose derivative fibres are briefly described and discussed in relation to the properties and uses of the fibres. C.

**Pe-Ce and Nylon Fibres: Characteristics.** G. Romeo. *Raion*, 1942, 10, No. 7-8, 18-19 (through *Chem. Zentr.*, 1943, i, 694, and *Chem. Abstr.*, 1944, 38, 3482<sup>1</sup>). Photo-micrographs of the two fibres are shown. The Pe-Ce fibre is almost insoluble in 10 per cent. caustic potash and 58° Bé sulphuric acid, which dissolve all other fibres. It is very soluble in xylene, which can be used to dissolve it from fibre mixtures. Nylon is very soluble in pure formic acid; it can be precipitated from the solution by dilution with water. It is soluble in concentrated sulphuric acid and in boiling 80 per cent. acetic acid, insoluble in concentrated calcium thiocyanate solution at 70°. It can be separated from cellulosic fibres by its behaviour towards sulphuric acid, from cotton by its action with acetic acid, and from silk and cellulosic rayon by its reaction with calcium thiocyanate. C.

**Polyfibre: Characteristics and Moulding.** W. C. Goggin and R. R. Bradshaw. *Modern Plastics*, 1944, 21, No. 11, 101-107, 164, 166. A form of Polyfibre based on polystyrene ranging in size up to 5  $\mu$  in diameter is discussed. In its simplest form the product is a bat of parallel fibres which has an apparent specific gravity of about 0.05. It can be used as thermal and sound insulating material and also as a replacement for kapok in applications requiring buoyancy. Poly-

fibre can readily be moulded and products of specific gravities ranging from 0.4 to 1.05 are feasible. Compression mouldings are characterised by high tensile and impact strengths. Bag moulding processes are applicable to Polyfibre; a description of one method is given. The greatest strength in a moulding is developed in a direction parallel to the fibres. For uniform strength in all directions bats are arranged with the fibres in adjacent lays at 90° to each other. The effects of moulding time, temperature and pressure and the solvent content of the fibre on the specific gravity and strength of moulded products, and the relations between the specific gravity and the strength, hardness, dielectric constant and water absorption are shown in a series of graphs and discussed. C.

**Textile Fibres: Damage by Light.** J. Salquain. *Teintex*, 1942, 7, 275-281, 303-307 (through *Chem. Zentr.*, 1943, 1, 1233, and *Chem. Abstr.*, 1944, 38, 3482<sup>a</sup>). The effect of natural and artificial light on fibres and the humidity factor are discussed. Exposure of cotton to ultra-violet light alters the fluorescence, and increases the alkali-solubility and the absorption power for Fast Red Salt NB and Variamin Blue B. The formation of carboxyl groups and increase in reduction power are shown by the copper number and other tests. The chemical changes are accompanied by a weakening of the fibres. The hydrogen peroxide formed by solar rays oxidizes alcohol and aldehyde groups of cellulose to carboxyl groups and causes the formation of oxycellulose. Probably a splitting of the glucopyranose groups of the cellulose chain takes place. Wool is attacked at the S-S linkages of cystine and sulphur is split off; a thio-alcohol is produced as well as the easily decomposed sulphonic acid, which is converted to several intermediate products and finally to sulphuric acid. Reactions of the basic groups and the increase of the ammonia nitrogen and the amine groups are discussed. The hydrolytic decomposition of wool is shown by its increased alkali and water solubility and lower strength and elongation. Even the wool of the living animal is damaged by the sun. Damaging effects are shown by certain unreduced vat dyes, such as Indanthrene Gold Orange 3G, and naphthol dyes, such as Naphthol AS-G. Complex oxidation reactions are responsible in which the dyes are reduced. Vat dyes that undergo this reaction are Cibanon Orange R, Indanthrene Brilliant Orange 3G, and others. Oxides of iron, titanium and zinc act as catalysts. Fibre-weakening dyes should be avoided and finished fabrics should be protected with yellow or green light filters. Naphthols and amines protect by combining with oxygen. Wool can be protected by chroming. Fibres damaged by bleaching or alkali are damaged by sun more readily than those that have not been weakened chemically. C.

**Yucca, Nolina, Agave and Sotol Fibre: Strength.** C. W. Botkin, L. B. Shires and E. C. Smith. *New Mexico Agr. Exp. Sta. Tech. Bull.*, 300, 1943, 38 pp. (through *Chem. Abstr.*, 1944, 38, 3480<sup>7</sup>). *Yucca glauca*, *Y. elata* and *nolina* are sufficiently abundant in New Mexico and yield enough fibre to serve as a possible source of hard fibre to replace imported jute and hemp. No significant difference in strength of fibre was found between air-dried and green plants. Bacterial retting was effective on either green or dry leaves; inoculations were necessary for the best decomposition of the dry leaf. Retting of *nolina* was unsatisfactory but autoclaving at 15 lb. for 80 min. with 2 per cent. soda ash freed the fibre. The average breaking lengths were, respectively, 47, 44.7 and 32.2 km. The two *Yucca* fibres are thus equal to hemp in strength, and *nolina* is equal to sisal, jute, sansevieria and raw silk. On drying for 28 days in a well-ventilated room the leaves lost, respectively, 48.4, 54.1 and 41.2 per cent. moisture. They contained 42.3, 43.0 and 48.5 per cent. crude fibre, 4.86, 5.16 and 3.22 per cent. ash, and 5.57, 6.50 and 4.30 per cent. protein. Similar data are presented for the stems of these plants and for *Y. baccata*, *Y. macrocarpa*, *Agave lechuguilla* and Sotol. C.

**American Upland Cotton: Staple Length.** J. H. Moore. *J. Amer. Soc. Agron.*, 1943, 35, 491-498 (through *Exp. Sta. Rec.*, 1943, 89, 662-663). Measurements of combed staple length on the cotton seed and commercial staple length of 325 samples from representative cotton varieties grown on North Carolina farms for two seasons indicated a correlation coefficient of 0.89 between the two measures of fibre length. Since combed staple length on the seed can be measured by relatively inexperienced help, that method should be used wherever possible. C.

**Textile Fibres: Density.** J. W. Illingworth. *Textile Recorder*, 1944, 62, August, 60-65; September, 57-61, 67. A useful review is given of modern work by Davidson, Speakman and others. C.

**Wool, Off-sorts: Percentage, Shrinkage and Value.** E. M. Pohle and H. R. Keller. *Sheep and Goat Raiser*, 1944, 24, No. 10, pp. 12-13. Range wool, representing the 1943 clip produced by the Rambouillet, Targhee, Corriedale and Columbia breeds at the U.S. Sheep Experiment Station and Western Sheep Breeding Laboratory, Dubois, Idaho, was graded, and sorted into a main sort and a number of off-sorts (burry, paint, low and stained, crutchings, tags and sweepings). All lots were sorted and scoured by a commercial scourer. A table shows the percentage of each sort in each grade, and also the shrinkage and the Boston grease wool value. W.

**White New Zealand and Angora Rabbits: Coat Variations.** T. M. P. Hardy and M. H. Markley. *J. Heredity*, 1944, 35, 183-192. Homozygous short-haired, heterozygous short-haired (carrier), and the undesirable long-haired ("woolly") pelts of the domesticated white New Zealand rabbit were examined microscopically and compared with the Angora rabbit pelt. The hair of the Angora rabbit was of lesser diameter and of greater length. In length, number of medullary cells, cross-sectional diameter, and ratio of guard hairs to under-fur, the hair of the carrier type pelt occupied a position intermediate to the short- and long-haired coats. The greatest difference between the normal and hybrid short coats of the New Zealand rabbit was in the cross-sectional diameters of the guard hairs at the zone above the skin where the fibre attains its maximum diameter, and it is planned to use this measurement as a basis for future studies. W.

**Cuticular Scales of Hair: Staining.** J. Davidson and W. D. Taylor. *J. Quekett Microscopical Club*, 1943, Series 4, I, 289-293. A staining method to show the cuticular scale pattern of animal fibres is described. The air is first driven out of the fibres by cutting and placing in distilled water in a vacuum embedding oven. Staining is also done in a vacuum oven, using dilute Carbol Fuchsin in distilled water. W.

#### (B)—YARNS

**Sheeting Yarns: Effect of Acid on Breaking Strength.** C. E. Morrill. *Amer. Dyes. Rept.*, 1944, 33, 320-321. Tests were made on a bleached sheeting with 21.97s warp and 21.85s weft yarns. Squares were immersed in acid solutions of concentrations varying from 0.01 per cent. to 0.03 per cent. c.p. sulphuric acid and changes in the breaking strengths of single warp and weft yarns were determined with an Incline Plane Serigraph Model I-P-2. The data are tabulated and curves are given showing average changes in strength of warp and weft yarns against acid concentration. The results indicate that the acid had approximately the same tendering action on both warp and weft threads in the same piece of cloth. C.

**Yarns: Acoustic Determination of Modulus of Elasticity.** J. W. Ballou and S. Silverman (E. I. Du Pont de Nemours & Co.). *Textile World*, 1944, 94, No. 7, 99; *Rayon Textile Monthly*, 1944, 25, 282. Brief reference is made to a method of determining the elastic modulus of yarn from its sound transmission. The yarn is held taut with one end held by a weight over a pulley and the other supporting a horizontal bar of steel about 8 ins. long. The bar is excited by a radio-tube audio oscillator and vibrates at the 10-kilocycle frequency, emitting a very high note. The yarn is thus set in vibration like a violin string and the wave-length is accurately measured by a sliding crystal. The velocity of the sound is calculated from the wave-length and frequency, and the density of the fibre substance is then introduced into the calculation to give the modulus of elasticity. The values obtained are two or three times greater than those given by slow loading or static tests. C.

**The Control of Counts.** "Questor." *Wool Rec.*, 1944, 66, 318, 360, 403, 447, 489, 532. The application is considered of accepted methods of quality control to woollen and worsted spinning, the maintenance of a steady average count, the location and assessment of sources of variation in yarns, and the accumulation of data regarding the variability of the product as a whole being discussed. Certain conditions necessary to the proper functioning of quality control are outlined, viz., the isolation of irrelevant variables due respectively

to the regain factor and to the length unit of measurement, the deliberate selection of samples in order to achieve either true randomness or an accepted bias, the choice of suitable "control points," etc. Particular problems relating to the woollen and worsted processes are indicated, and it is shown how the use of quality control methods can increase the scope and the responsibility of the testing department. The final article discusses the research value of treating routine test methods by statistical means, and suggests the large part that an adoption of quality control methods might play in the future technical progress of wool spinning. W.

#### (C)—FABRICS

**Hosiery Abrasion Testing Machines: Comparison.** Margaret B. Hays and Dorothy C. Caudill. *Textile Research*, 1944, 14, 183-187. Tests were made on two constructions of Sea Island cotton hose (A) from 90s/2 yarns reinforced with a second 90s/2 yarn in the heel, sole and toe; (B) from 120s/2 yarns reinforced through the heel, sole and toe with an additional end of 90s/2 yarn. In the first testing machine cut toe and heel portions were mounted on a circular holder which revolved 60-70 times per minute beneath two fine abrading wheels which exerted a normal pressure of 500 gm. The counter reading was recorded when a hole was worn through in a section. In the other testing device the hose were placed on leg forms arranged so that the parts to be tested came into contact with cylinders around which strips of duck material were wound. The pressure against the cylinder on the toe was 485 gm. and the heel pressure 735 gm. The cylinders oscillated 40 cycles per minute. The results of tests on the toe and heel portions of 25 hose with the first machine and 50 hose with the second, and also of tests of high heel portions on the second machine are tabulated and discussed. Both machines showed that Construction A was more resistant to abrasion than Construction B and that no significant difference existed between the resistance to abrasion of the toe and heel. More cycles were required to produce a hole with the second machine than with the first. The random sampling error was less with the first machine than with the second. The first method required half as many test hose (but twice as many determinations) as the second. The second method required more time per hose, both as elapsed time and as operator time. C.

**Fabric: Determination of Air-permeability.** S. G. Popov and S. P. Palazov. *Izmeritelnaya Tekh.*, 1941, 3, No. 5, 27-32 (through *Chem. Zentr.*, 1943, i, 1345 and *Chem. Abstr.*, 1944, 38, 3482<sup>a</sup>). Devices suitable for determinations of the air-permeability of fabrics and formulae that can be used for evaluating the results are discussed. C.

**Fabrics; State of Tension in —.** W. Weltzien. *Monatsh. Seide Kunstseide*, 1939, 44, 429-430; *Mitt. Textilforsch.-Anstalt Krefeld*, 1939, 15, 80-81; 1941, 17, 7-11, 14-16 (through *Chem. Abstr.*, 1944, 38, 3482<sup>a</sup>). The results of various physical tests on silk, rayon, staple fibre, mercerised cotton, etc., are discussed. C.

**Quality Control Charts: Application in Textile Mills.** A. G. Ashcroft. *Textile World*, 1943, 93, No. 12, 69-71. A general account is given of the utility of Quality Control Charts as an aid to manufacturers working to the strict requirements of American service specifications. The following examples are reproduced. (1) Control of weight, strength, and yarns per inch of Army blanket; (2) The same for hard-texture duck; (3) Record of the porosity of cotton duck. C.

**Salt Spray Test Cabinet: Fog Calibration.** V. M. Darsey. *A.S.T.M. Bull.*, 1944, No. 128, 31-34. The salt spray test is a method of producing accelerated corrosion of articles placed in a finely divided dense wet fog produced and maintained by atomizing a 20 per cent. solution of sodium chloride with air inside a cabinet at 92-97° F. The deficiencies of the methods used for calibrating the fog inside a salt spray cabinet are pointed out. A report is given of investigations of the humidity produced by atomizing salt solutions of different concentration inside a test cabinet, and of the relationship between the humidity and the sodium chloride content of the fog. A method of calibrating the fog is suggested which depends on collecting a solution of fog in the cabinet and determining its salt concentration. A daily operating record of a large salt spray cabinet is presented. Various important factors in salt spray testing are considered. C.

**American Cotton Dress Fabrics: Quality, 1942 and 1943.** P. E. Keeney. *Missouri Sta. Res. Bul.* 375, 1943, 19 pp. (through *Exp. Sta. Rec.*, 1944, 90, 281-282). The fabrics for this study included percale prints, gingham, chambray, seersucker, light weight muslins, lawns and dimities, and were purchased from local stores in two groups, including 68 fabrics purchased in the spring of 1942 and 42 in February, 1943. Prices ranged from 19 to 79 ct. in 1942 and from 23 to 79 ct. in 1943, averaging 37 and 45 ct., respectively. Chambrays, gingham and lawns were higher priced in 1943. Lower thread count, more sizing, greater fabric strength (due to larger and stronger yarns), and little difference in shrinkage were observed in the 1943 purchases as compared with those for 1942. The majority of the fabrics purchased exceeded 2 per cent. shrinkage in both warp and weft. Most of the fabrics showed little loss of colour by crocking; only 12 per cent. of those purchased in 1942 and none in 1943 showed loss of colour by bleeding; 70 per cent. of the 1942 purchase and 64 per cent. of the 1943 purchase showed loss of colour in laundering; approximately 27 and 37 per cent. of these two groups, respectively, failed to show loss of colour after 40 hours' exposure in the Fade-Ometer. In all tests for colour fastness the percale prints showed the greatest tendency toward loss of colour. Rose, green, tan and blue showed the least colour permanency. Tests of house dresses are also noted. C.

**American Drapery Fabrics: Quality, 1942 and 1943.** P. E. Keeney. *Missouri Sta. Res. Bul.* 374, 1943, 18 pp. (through *Exp. Sta. Rec.*, 1944, 90, 282). The draperies studied were purchased at three stores (in Missouri) in two groups consisting, respectively, of 40 fabrics of varied textures, colours, designs and prices purchased in June, 1942, and representing goods of pre-war fabrication, and 24 fabrics purchased in February, 1943. In both groups the majority of the fabrics were of cotton; the few containing rayon or linen were considerably more expensive than the cotton. Widths varied from 35 to 53 in., the majority (70 per cent.) being 48 in. wide. Weight per sq. yd. varied from 3.2 to 10.3 oz., with a range of from 5.0 to 7.7 oz. for the majority of fabrics. Very little relationship existed between the weight of the fabric and its construction and durability due to wide variation in strength and structure of the yarns, and price was no indication of durability. Fabrics purchased in 1943 had lower thread counts, without the expected decrease in strength, than those obtained in 1942. Greater shrinkage in laundering and dry cleaning was apparent, however, in fabrics purchased in 1943. The few labels pertaining to shrinkage that appeared on fabrics were found to be dependable. The label information pertaining to colour fastness was not very reliable, however, according to the results obtained in colour fastness tests. Of the fabrics purchased in 1942, 19 showed no loss of colour after 80 hours of exposure in the Fade-Ometer, as compared with 5 fabrics purchased in 1943. C.

**American Service Clothing: Physiological Testing.** *Textile Research*, 1944, 14, 222-227. In physiological testing, as practised by the American Quartermaster Corps, climatic conditions representative of the area for which the garment is designed are selected and reproduced. Garments for arctic use are tested at temperatures down to  $-40^{\circ}\text{F.}$ , with or without wind, and those for tropical use at  $85^{\circ}\text{F.}$  and 85 per cent. R.H. Rain or snow may be added. Measurements are made of skin temperatures, sweat rates and *Clo* values, the *Clo* being the amount of insulation provided by a suit which affords comfort, at least to the average American, at  $70^{\circ}\text{F.}$  when he is inactive in still air. Investigations have shown that gloves or mittens constructed of materials known at present cannot keep the hands of inactive persons adequately warm at temperatures much below freezing. Increases in thickness are accompanied by disproportionate increases in radiating surfaces and by losses in dexterity. Wool pile fabrics half an inch thick are suitable for cold weather clothing. As a result of tests of clothing for tropical climates, preferences have been expressed for poplin. Lighter weight and thinner textiles impose less heat stress as measured by the sweat rate, and close, tight weaves materially reduce mosquito bites. Investigations of garments intended for protection against rain have resulted in the development of a garment made from coated Nylon. C.

**Clothing Fabrics: Functional Characteristics.** G. F. Doriot. *Textile Research*, 1944, 14, 217-219. A report of an address. It is suggested that the textile and clothing industries should encourage young men to embark early on a career of training, and to specialise in a particular phase. Army experience

of discomfort in the wear of clothing impermeable or permeable to vapour and of a pattern of wear which is associated with some physical property only doubtfully represented by tensile and tearing strength is discussed, and it is suggested that the industry could profitably have applied its scientific ability to such problems and to the study of the durability, functional characteristics and performance required by the consumer. C.

**Textile Fabrics: Warmth.** J. W. Illingworth. *Textile Recorder*, 1944, 61, March, 56-59; April, 55-60; 62, June, 60-64; July, 67-70, 73. The thermal properties of clothing fabrics are reviewed in the light of modern research, under the headings (1) physiological aspects, (2) body temperature, (3) desirable attributes of clothing, (4) the importance of entrapped air in clothing, (5) the Kata thermometer, (6) constant temperature methods of test, (7) effects of cloth thickness and density, weave, multiplicity of layers and closeness of fit, (8) effects of air movement and humidity, (9) effect of washing and finishing, (10) surface emissivity, (11) moisture content and cold feel, (12) moisture permeability, (13) thermostatic effect of moisture, (14) comparisons of various fibres, (15) protection from sunburn, (16) all-wool and part-wool blankets, (17) part-wool clothing, (18) asbestos and glass fibres, and (19) protection from exposure. C.

**Sampling Plan for Wool Textiles.** Philadelphia Quartermaster Depôt. *Text. World*, 1944, 94, No. 5, 88-89. The plan is designed to measure, in addition to width and length, the following attributes observed by visual inspection and not by laboratory tests: (a) shade, from side to side, or from end to end; (b) shivy material; (c) slubby material; (d) holes; (e) coarse yarn. A rejected piece of material is defined as being more than  $2\frac{1}{2}$  per cent. defective. The sampling plan, which is a double one, is a compromise between an average out-going quality level and lot-by-lot acceptance, and is a 10 per cent. consumer risk. Tables show the classification of fabrics into 3 groups (purpose for which used, cost, and urgency of the need), and the corresponding sampling required. W.

#### (D)—OTHER MATERIALS

**Textile Preservatives: Testing.** H. J. Bunker. *Proc. Soc. Agr. Bacteriologists*, 1943, 9-12 (through *Chem. Abstr.*, 1944, 38, 3483<sup>8</sup>). Pieces of fabric are treated with preservatives, then fixed on aluminium frames and buried vertically in a typical light garden soil, kept at 30° and 20 per cent. water content. They are tested weekly for strength by attempting to tear them by hand. C.

**Vinyl Chloride-Acetate Non-rigid Resin Compounds: Stiffness and Brittleness.** R. F. Clash, Jr., and R. M. Berg. *Modern Plastics*, 1944, 21, No. 11, 119-124, 160. The cantilever beam test for the determination of the stiffness in flexure of non-rigid plastics (A.S.T.M. D747) and a torsion test ("Flex Test") for stiffness are discussed. Data are presented showing agreement between results obtained by the two methods for compounds containing 25-45 per cent. dioctyl phthalate in vinyl chloride-acetate resin VYNW at temperatures in the range -56.7° C. to 25° C. An apparatus for testing brittleness which conforms to the requirements of A.S.T.M. D746 is also described. Results are expressed as brittleness temperature, i.e. the lowest temperature of non-failure of five consecutive test specimens of a given material when struck by a moving arm under specified conditions. Results of stiffness and brittleness tests on three series of plasticized compounds based on vinyl chloride-acetate resin VYNW and a range of concentrations of tricresyl phosphate, dioctyl phthalate, and trioctyl phosphate plasticizers, respectively, are discussed. Inverted "S"-shaped families of curves are obtained representing the log stiffness-temperature function for these plasticizers in the concentration range 25-45 per cent. Plasticizer addition above 25 per cent. appears only to translate the curves toward lower temperatures. The brittleness contour superposed on the stiffness curves shows that impact failure is not simply related to stiffness but includes other factors, among them plasticizer type and concentration. The three plasticizers have the same sort of effect on both properties but to widely different degrees. The curve showing stiffness at 25° C. as a function of dioctyl phthalate concentration also has a characteristic inverted "S" shape. C.

**Drop Ball Impact Testing Machine: Application to Plastics.** G. Lubin and R. R. Winans. *A.S.T.M. Bull.*, 1944, No. 128, 13-18. The Izod-type pendulum machine is not suitable for determining the shock resistance or impact strength of plastics, and a drop ball impact machine is described and shown in photo-

graphs. Izod specimens with the notch milled in on the face are used. The single-blow test consists of dropping hardened steel balls by means of a special electro-magnet on to the specimen supported in a vice. The height of drop can be varied. For multi-blow impact fatigue tests an arrangement is provided for delivering a ball every 4 to 10 sec. to the magnet. An automatic cut-off stops the machine when the sample is broken or cracked. Three methods of testing are described. Results obtained in tests on laminated phenolic, moulded phenolic and thermoplastic materials are presented in tables and graphs, and are compared with results obtained with the Izod pendulum machine. Photomicrographs showing types of fractures are given. C.

## PATENT

**Quality Control Calculating Device.** Bellings & Lee Ltd. and C. W. Heath. B.P. 564,520 of 4/3/1943:2/10/1944. A calculating device for performing industrial quality control calculations comprises a base bearing a calibrated circular or part-circular scale, a disc or part of a disc rotatable about the centre of the scale and bearing a zero datum line or equivalent marking disposed adjacent the scale to co-operate therewith, and a linear scale rotatable about the centre of the disc and slidable radially thereof, the disc or part of a disc bearing a number of predetermined curves originating from the zero datum line. Details of the method of operation are given. C.

## 7—LAUNDERING AND DRY-CLEANING

## (A)—CLEANING

**Soaps: Wetting Action.** Sadgopal. *Soap, Perfumery Cosmetics*, 1944, 17, 258-259 (through Chem. Abstr., 1944, 38, 3501<sup>1</sup>). The Na and K soaps of fatty acids from  $C_4$  to  $C_{18}$  have very little wetting action on soiled fabrics. This action begins with soaps of both saturated and unsaturated  $C_{12}$  to  $C_{20}$  fatty acids. Ricinoleates possess very little wetting action. The myristates have the maximum wetting action of the saturated acids. Oleates are better than linoleates and K soaps are better than Na soaps. The action of soaps is dependent on the total predominant fatty glyceride components. The soaps of castor oil rich in ricinoleic glycerides have very little wetting power, whilst almond, olive and sesame and other oils, rich in oleic glycerides, have good wetting activity. Soaps of hard fats like mahuwa and tallow are good wetting agents at high temperatures. Coconut soaps possess the best wetting properties because of their richness in myristic glycerides. Soaps from hardened fats possess poor wetting activity. Wetting action is high at high temperatures. Rosinates, however, have less wetting action at high temperatures. C.

**Fabrics: Laundering; Losses due to Lint Formation.** W. Kind and O. Oldenroth. *Bastfaser*, 1942, 2, 147-153 (through Chem. Zentr., 1943, i, 1014 and Chem. Abstr., 1944, 38, 3846<sup>3</sup>). Linen, twill and satin fabrics were laundered in a 35 kg. drum. Losses due to lint formation were determined after 5 and 50 washings by weighing the samples and by filtering the lint from a measured amount of the wash water. Experiments with various sudsing materials indicated that the usual suds, consisting of large bubbles, have no protective properties. An increased rate of rotation of the drum causes greater lint formation. The strength of the washing solution is of little significance; the chief losses appear only in rinsing. Prolonged dry running of the washing drum when the washing solution is changed is harmful. C.

**Sodium Secondary Alkyl Sulphates: Detergency; Effect of Electrolytes.** R. G. Aickin. *J. Soc. Dyers & Col.*, 1944, 60, 170-176. An account is given of investigations of the effect of the addition of various alkali metal and alkaline earth halides on the removal of olive oil from wool by secondary alkyl sulphates. Data showing the effects of electrolyte concentration, temperature and pH are presented. It is found that the initial reduction in the efficiency of the process brought about by addition of electrolytes is followed by a very large increase in the efficiency at higher concentrations. The electrolyte effect is largely due to the ions of sign opposite to that of the long-chain ions, and divalent ions are much more effective than the univalent ions. The various univalent ions fall into a series as regards their influence, viz.  $K > NH_4 > Na > Li$ . The observed effects are explained in terms of the interfacial forces, viz. those existing between the oil, the detergent solution and the textile fibre, which are involved in the actual removal of the oil from the fibre. Another major factor

involved is that of the stability of the emulsion produced by dispersion of the removed oil in the detergent solution. C.

#### PATENTS

**Control Means for a Power Actuated Machine.** H. H. Brownlee. B.P.564,605 of 12/1/1943:5/10/1944. In a garment press of the polished head type a device is usually fitted to ensure that the operator has to use both hands to close the press, but the danger to bystanders is not thereby removed. This specification describes a means for opening the press immediately anyone comes within a predetermined distance from it, and of closing it again when they leave this area. Further, the press can be made to open when the garment is dry. The control is based on a magnetically operated air valve which is made to function by suitable valve circuits. The metalwork of the press forms part of the input circuit to a three-electrode valve, and a series of relays culminating in the air valve are connected in the output circuit. The characteristics are arranged so that when the press is unattended it automatically shuts; when a person approaches within a certain distance of the press, the characteristics are changed and the press immediately opens. By incorporating a moisture or thermostatic switch in the back of the press, it can be made to open when the garment is dry. La.

**Control-Means for a Machine adapted to operate on Moist Articles.** H. H. Brownlee. B.P.564,606 of 12/1/1943:5/10/1944. The object of this invention is an improvement of the means whereby a garment press is automatically opened when the garment has reached a definite state of dryness. The operator has to close the press by operating two manual switches, but these open on being released. As soon as the head comes into contact with the wet garment, current is made to flow in the plate circuit of a valve so that a magnetically operated air valve keeps the press closed. When the garment has reached a certain state of dryness, the plate current is reduced and the air valve allows the press to open. The arrangement can also be controlled by thermostatically operated contacts in the head of the press and a simplified circuit. La.

**Improved Process and Apparatus for Treating Liquid.** W. Paterson. B.P.564,708 of 3/4/1943:10/10/1944. This invention is an improvement of the continuous flow softening process described in B.P.10,719 (1902), and is of particular use in the lime softening of water. The liquid is mixed and agitated with previously formed sludge or other catalytic agent and fresh reagent in a special tank. The tank is arranged so that the mixture travels from one end to the other in a horizontal direction and during its passage through the tank the mixture is subjected to a spray or cascade of the sludge or catalytic agent. The sprays are produced by power-driven means and the method ensures effective treatment without short circuiting by the raw water. La.

## 8—BUILDING AND ENGINEERING

### (D)—POWER TRANSMISSION

**Lubricating Oil Addition Agents.** R. Schnurmann. *Chemical Products*, 1944, 7, 56-60. Addition agents for lubricating oils are classified into (1) extreme pressure additives, (2) viscosity index improvers, (3) pour point depressants, (4) oxidation inhibitors, (5) bearing corrosion inhibitors, and (6) detergents, and are briefly discussed. C.

### (F)—LIGHTING

**Textile Mills: Scientific Lighting.** J. W. Howell. *J. Soc. Dyers & Col.*, 1944, 60, 161-170. Sight and seeing, the process of seeing, accuracy of seeing, light measurement and the adequacy of illumination are briefly discussed. Lighting requirements in wool grading and sorting, healding or drawing-in, weaving, perching, dyeing and printing departments are studied, suitable lighting arrangements, including systems employing fluorescent tubes are considered, and photographs are given. Data are presented showing increases in output and quality, and the net profits resulting from better lighting in worsted weaving, and silk and rayon warping and weaving processes. The use of day-light lamps and other colour corrected sources, particularly for colour matching, is discussed. The use of infra-red lamps for heating is also discussed. C.

## (G)—HEATING, VENTILATION AND HUMIDIFICATION

**Electrostatic Air Cleaning System.** Judson Mills Inc. *Textile World*, 1944, 94, No. 6, 88-90. An illustrated account is given of an air-conditioning system equipped with an electrostatic "precipitron" supplied by the Westinghouse Electric Co. Air is supplied by a 60-h.p. electric blower to a set of four precipitrons, each dealing with 125,000 cub. ft. per minute. The deposited dirt is washed off each unit in turn, by hand, and allowed to pass to the drain. The ionizing section of the precipitron operates with a 13,000 volt charge and the collector section with 6,000 volts. These d.c. voltages are supplied from a 115-v. a.c. unit. The power consumption is about 15 watts per 1,000 cub. ft. of air per minute. In the winter air is re-circulated and only about 10-15 per cent. is taken from outside. In summer, fresh air only is circulated. The weaving shed was kept for a year at 82-85° F. (even on a day when the outside temperature was 98°) and the relative humidity was controlled as required between 70 and 80 per cent. C.

**"Precipitron" Electrostatic Dust Precipitator.** *J. Appl. Physics*, 1944, 15, No. 7, xvi. In the electrostatic unit known as the Precipitron the generation of ozone by the discharge current has been reduced to such a point that the ozone concentration in the air is no more than that found in outdoor air in bright sunlight. A compact unit small enough to be placed in an ordinary window has been developed. Industrial uses of the Precipitron for removing oil mist, dust, pollen, etc., are mentioned. C.

## (H)—WATER PURIFICATION

**Lime-Soda Water Softening Plant: Automatic Control.** F. A. Champion. *J. Soc. Chem. Ind.*, 1944, 63, 204-208. An automatic method has been devised in the laboratory for controlling lime-soda softening of a variable mixture of several constituent waters, when each of the latter is of reasonably constant composition. Theoretical consideration of such general cases, and experimental work on an actual water of this type, have shown that the quantity of reagents required per gallon of raw water is proportional to the conductivity of the latter. The rate of flow of the raw water may be measured by noting the effect of the variable level of the water above a weir on the resistance of a partly immersed conductivity cell of special design. By suitably shaping the electrodes, this cell may be used to measure both the hardness and the rate of flow of the water and hence to determine the quantity of reagent required per hour for softening. Thermionic relays incorporating automatic temperature correction are suggested for using the resistance of this dual-purpose cell to operate an electrical device, such as a solenoid, which, in turn, controls the valve of the dosing gear. Three examples of suitable dosing gear are outlined. C.

**Water for Textile Processing: Quality and Treatment.** L. B. Miller. *Cotton (U.S.)*, 1944, 108, No. 7, 85-88, 132-133. A general review of natural water supplies, constituents that are deleterious in textile processing, softening, removal of iron and manganese, bacterial growths in pipes and tanks, turbidity and colour, microbiological growths, and pollution of supplies. A textile process water should have as maximum limits: hardness 50 parts per million (as  $\text{CaCO}_3$ ), Fe 0.2, Mn 0.1, heavy metals *nil*, turbidity 25 and colour 50, p.p.m. C.

**Water Softening and Filtration Plant.** *Rayon Textile Monthly*, 1944, 25, 299-302. A general account is given of the zeolite process for softening water, with illustrations of single-unit and triple unit filters and a zeolite softener (Graver Tank and Manufacturing Co.), a filtration plant and a zeolite installation (Roberts Filter Manufacturing Co.), and a water softening installation with selective-automatic valve control (Refinite Corporation). Mention is also made of a coagulator and a filter for caustic liquors in mercerising or caustic soda recovery (Hungerford and Terry Co.). C.

## (I)—WASTE DISPOSAL

**Mercurial Ointment: Preparation.** N. A. Kessler and H. G. DeKay. *J. Amer. Pharm. Assoc.*, 1944, 33, 118-122 (through *Chem. Abs.*, 1944, 38, 2790). Formulæ are given for improved dispersion and precipitation methods for preparing mercurial ointment. Various substances, including wool fat, are capable of dispersing mercury, wool fat being a better dispersing agent for mercury than mercury oleate. W.

## PATENT

**Sleeve Air Filter.** C. C. Marston. B.P. 564,161 of 12/1/1943:15/9/1944. An air or gas filter comprising a hollow textile member (e.g. a sleeve) through which dust-laden air or gas passes for filtering is fitted with power-driven means for continuous and regular mechanical shaking, and is divided into a number of non-extensible parts by one or more interposed resiliently extensible sections. The latter may consist of a resilient section such as of elastic material (e.g. elastic webbing or other elastic fabric) which will enable the sleeve to be hung taut and to be further tautened or extended and released evenly without undue shock or strain. C.

## 9—PURE SCIENCE

**Nitrocellulose Molecules: Weight and Shape.** H. Campbell and P. Johnson. *Trans. Faraday Soc.*, 1944, 40, 221-233. Viscosity, sedimentation velocity, and diffusion measurements have been made on solutions in acetone of some commercial nitrocelluloses, and compared with similar measurements on the so-called globular proteins. By means of equations connecting viscosity and molecular shape, and my making certain assumptions, molecular weight values have been calculated for nitrocellulose fractions from viscosity measurements. For the calculation of molecular weight from sedimentation velocity and diffusion measurements, the experimental requirements for accurate work are pointed out. The dangers of extrapolating to zero solute concentration from measurements on solutions of too high solute concentration are emphasized. Until molecular weights of many fractions of nitrocellulose have been accurately obtained, no decision regarding the validity of the viscosity equations can be attempted. Data so far obtained are in agreement with the view that the nitrocellulose molecule in acetone is a long, almost completely stretched chain of nitrated glucosidic residues, the chain diameter of which is considerably increased by solvation, and in which some little flexibility may be assumed. C.

**Polyvinyl Chloride: Rheological Properties.** L. Bilmes. *J. Soc. Chem. Ind.*, 1944, 63, 182-184. The rheological properties of plasticised polyvinyl chloride have been studied in a specially constructed torsion apparatus over the temperature range  $-70^{\circ}$  to  $100^{\circ}$ . The results are analysed by means of the Nutting equation,  $\psi = S\beta\sigma^{-1}t^k$ , where  $S$  is the shearing stress,  $\sigma$  the strain,  $t$  the time,  $\psi$  the firmness, and  $\beta$  and  $k$  are constants. On raising the temperature from  $-70^{\circ}$  to  $+140^{\circ}$  the material passes through glassy, leathery, rubbery and plastic states, and it is possible to characterise these states by the values of  $\psi$  and  $k$  associated with them. The rheological properties of the different grades of polyvinyl chloride tested appeared to differ only in being displaced over a temperature scale. Increasing the plasticiser content shifted the  $\psi$ /temperature and the  $k$ /temperature curves towards the lower end of the temperature scale. C.

**Fluorescent Lamps: Cross-prism Investigation.** F. E. E. Germann and R. Woodriff. *Rev. Sci. Instruments*, 1944, 15, 145-149. A cross-prism method is described whereby a single photograph of a fluorescence spectrum gives directly both intensity and spectral distribution of fluorescent light produced by exciting light of all wave lengths. A vertical scanning of such a photograph gives the variation of light intensity of a given wave length as a function of the exciting wave length. A horizontal scanning gives the spectral energy distribution as a function of wave length for a given frequency of exciting light. With a continuous source of ultra-violet radiation, a single exposure thus gives all information necessary to determine the best frequencies of exciting light to produce a maximum fluorescent light of a given colour or energy distribution. C.

**Fats and Fatty Acids: Unsaturation and Ultra-violet Absorption Spectra.** R. H. Barnes, I. I. Rusoff, E. S. Miller and G. O. Burr. *Ind. Eng. Chem., Anal. Edn.*, 1944, 16, 385-386. The spectral absorption of several unsaturated fatty acids and natural fats has been measured from 2,500 to 2,100 Å. Data are presented that show a definite relationship between the degree of unsaturation and extinction coefficients at 2,100 Å. It is possible to predict the extent of absorption at this wave length by natural fats from a knowledge of their compositions. C.

**Workshop Microscope.** Messrs. Machine Shop Equipment Ltd. *Engineering*, 1944, 158, 216; *Industrial Chemist*, 1944, 20, 508. A brief description is given of a compact microscope for direct application to machine parts. The magnification is  $\times 40$  and the field of view about 0.2 in. diameter. The optical system is a  $1\frac{1}{2}$ -in. objective and micrometer eyepiece containing a scale graduated in 100 divisions of 0.001 in. The eyepiece can be focused independently to give a sharp image of the scale. Lighting is from the mains or a No. 8 dry battery. C.

**Starch Suspensions; Depolarization of Light by —.** A. Boutaric and M. Chapeaux. *J. chim. phys.*, 1942, 39, 73-76 (through *Chem. Zentr.*, 1943, i, 255-256 and *Chem. Abstr.*, 1944, 38, 2869<sup>3</sup>). To check the unexpected experimental results of Calinicenco, rice starch suspensions previously heated to 71, 77, 82 and 90° were examined as to change in optical density and degree of depolarization. From the curves it appears that the degree of depolarization diminishes for equal concentrations with rising temperature (agglutination), but does not reach zero. For equal temperatures the coefficient of depolarization at first rises steeply with increasing concentration and then approaches a limiting value asymptotically. The depolarization does not seem to be necessarily bound to the presence of doubly refracting particles. C.

**Cellulose Ester, Gelatin and Polyvinyl Derivative Discs: Electrical Anisotropy.** S. E. Sheppard and P. T. Newsome. *J. Chem. Phys.*, 1944, 12, 244-248. A number of colloid materials, including proteins and cellulose and polyvinyl derivatives, were obtained in sheet form and stretched to elongations of 100 per cent. or more. Circular discs were cut from the sheets and their degree of orientation measured in an alternating electric field. The relation of the orientation to field strength, thickness, humidity and moisture content is discussed. The results show that the property of electrical anisotropy, induced by stretching, is not displayed by all kinds of natural and synthetic colloids, but is limited (a) to those containing an appreciable amount of fixed hydroxyl and/or absorbed water, and (b) those capable of absorbing considerable amounts of water. With gelatin and hydrolysed cellulose acetate, the electrical anisotropy varies with absorbed water content, but with polyvinyl alcohol it is independent of the water content. C.

**Organic Plastics: Effect of Temperature on Mechanical Properties.** T. S. Carswell and H. K. Nason. *Modern Plastics*, 1944, 21, No. 10, 121-126, 158, 160. The tensile stress-strain curve of organic plastics is discussed and the characteristic features of the curves associated with different types, e.g. soft, weak and hard, tough materials are, indicated. With all true thermoplastics the slope of the initial Hookean or elastic portion of the stress-strain curve decreases, the magnitude of the maximum stress at the yield point decreases, and the point of rupture tends to move along the curve toward higher values of strain as the temperature is increased. Thermosetting materials show the first two changes, although to a less degree than thermoplastic materials, and a tendency to the third. A plastic which is tough and ductile at room temperature, e.g. cellulose acetate, may become brittle and hard at low temperatures, and plastics which are brittle and hard at room temperatures, e.g. polymethyl methacrylate, may become tough and ductile at elevated temperatures. Because of variations in stress distribution and in magnitude of combined stresses (tension, compression and shear) acting simultaneously, it is possible for a material, held at constant temperature, to be tough and ductile under one set of conditions, but brittle and hard under another. Curves showing the effect of temperature on the tensile strength, yield stress, extensibility, modulus of elasticity, compressive strength, flexural strength, shear strength and impact strength of several plastics are presented and briefly discussed. An extensive bibliography is given. C.

**Formaldehyde: Effect on Protein.** S. Fiala. *Naturwissenschaften*, 1943, 31, 370 (through *Chem. Abs.*, 1944, 38, 2053). The effect of formaldehyde on protein was studied polarographically. Protein in borax-buffered solution (pH 7.9.5) shows upon addition of formaldehyde an immediate lowering of the double wave of the protein in the polarogram. The lowering is proportional to the formaldehyde concentration, to pH and to temperature. The process is irreversible. The result contradicts the hydrolysis theory of the formaldehyde effect, but points toward aggregation or condensation of protein molecules.

This is confirmed by the increased surface tension and the lowered protective colloid action of formaldehyde-treated protein. W.

**Fibrous Proteins: Combination with Acids.** G. A. Gilbert and E. K. Rideal. *Proc. Roy. Soc. A.*, 1944, 182, 335-346. An approximate titration equation is developed for the reaction between fibrous proteins and acids, in which account is taken of the valency and intrinsic affinities of the acid anions and of the limited number of adsorption sites available for anions. The differences between this hypothesis and that of Steinhardt and Harris (these *Abs.*, 1940, A291) are indicated. W.

**Protein-formaldehyde Reaction: Wool.** E. R. Theis and M. M. Lams. *J. Biol. Chem.*, 1944, 154, 99-103. After reaction with formaldehyde, the amount of acid or base with which wool combines is unaltered over the pH range 1-9.5, but it combines with a slightly larger amount of base at >pH 9.5. At pH 1-5 formaldehyde combines with acid amide and/or imino groups of the polypeptide chain. In addition, it combines with the imidazole group of histidine at >pH 6.1 and with the terminal amino group of lysine at >pH 10.5. At pH 9.5-12 wool combines with more formaldehyde than corresponds to the lysine content, this difference being probably due to reaction of the formaldehyde with the wool sulphur. W.

**Reaction of Formaldehyde with Keratin.** J. L. Stoves. *Nature*, 1944, 154, 272-273. On the basis of supercontraction experiments it is suggested that new cross-linkages are formed in wool and deaminated wool fibres by treatment with formaldehyde at pH 1 and 10.5 for 1 hr. at 100°. These linkages are not formed in either normal or deaminated fibres by treatment with formaldehyde at pH 5 and 100° for 1 hr. W.

**Wool Blends: Spectrophotometric Prediction of Colour.** E. I. Stearns and F. Noechel. *Amer. Dyes. Rep.*, 1944, 33, 177-180. An empirical relation has been derived between the reflection coefficient of the components of a blend and the reflection of the blend, for any particular wave-length. By means of this relation the spectral reflection curve of the blend can be obtained from that of the components. Diagrams are given showing the close agreement between the calculated and observed curves for a number of blends. For wool the relation is:

$$100 \frac{100-R}{0.15(R-1)+1} = \frac{100-R_1}{0.15(R_1-1)+1} + b \frac{100-R_2}{0.15(R_2-1)+1}$$

where R = the percentage reflection of the blend,  $R_1$  and  $R_2$  = the reflection of components and a and b = the percentages of the components in the blend. W.

#### PATENTS

**Soluble Starch: Production.** M. D. Rozenbroek (Netherlands; vested in U.S. Alien Property Custodian). U.S.P. 2,338,457. Powdered starch containing 8-20 per cent. of moisture is mixed with about 15 parts by weight of sodium carbonate and then treated with chlorine gas at a temperature below 60° C. The amount of chlorine passed in is about 6 per cent. of the weight of starch. C.

**Carbamylethyl Cellulose Ester: Production.** Röhm & Haas Co. U.S.P. 2,338,681. Cellulose is caused to react at 0-40° C. with acrylamide in the presence of a strong base (10-40 per cent. aqueous solution) until carbamylethyl groups are introduced into the cellulose and some part of them have been further hydrolyzed to carboxyethyl groups. At least 0.2 mol. of acrylamide is used for each glucose unit. C.

**Cotton Plant: Metabolism.** F. J. Richards. *Ann. Botany*, 1944, [New Ser.], 8, 43-55. The methods used by Mason and Phillis in analysing their data are examined and it is shown that many of their conclusions and theories are not supported by the data. Without further experimental evidence, supplemented by adequate statistical analysis, both the water-content relations and the partitioning between soluble and insoluble fractions of N, P and carbohydrate are more complex phenomena than envisaged by Mason and Phillis. C.

**Inter-specific Cotton Hybrid: Fertility.** S. Nakatomi. *Plant Breed. News*, 1934, 9, 548-549 (through *Plant Breed. Abstr.*, 1944, 14, 226). An  $F_1$  plant from the Egyptian Ashmouni ( $n=26$ ) × a Manchurian variety (*G. herbaceum*,  $n=13$ ) bore no seed when selfed, but on being pollinated by Kings Improved

(*G. hirsutum*,  $n=26$ ) gave a few seeds. A plant raised from among these flowered abundantly and was partly fertile, selfed or crossed. It had  $n=26$  chromosomes. C.

**Polyploid Cottons: Cytology.** A. J. T. Mendes. *Bragantia*, São Paulo, 1942, 2, 101-110 (through *Plant Breed. Abstr.*, 1944, 14, 226). In a study of polyploid cottons obtained by colchicine treatment, immersion of delinted seeds in a 0.15 per cent. solution for 16 hours was found to be most effective. Some plants of *G. hirsutum* failed to react at all, whereas in *G. herbaceum* all plants reacted equally. Most of the roots of the abnormal looking plants of *G. hirsutum* proved to contain a mixture of tissues with  $2n=52$  and  $2n=104$ ; flowers with mixed tetraploid and octoploid tissue were also encountered. At anaphase I in the octoploids 52 chromosomes generally went to each pole, but various deviations were also occasionally observed. Secondary association was of frequent occurrence. Pollen formation was more or less normal but the anthers mostly failed to dehisce. The pollen was larger and more variable in size than in normal plants. No seed was obtained either from self-pollination or from cross-pollination with either octoploid or tetraploid. Occasional fruits were formed from open pollination; the seeds obtained, which were usually abnormally large, could often be induced to germinate only by incision of the testa. The plants produced frequently had  $2n=52$  chromosomes. C.

**Mechanical Wood Pulp: Attack by Fungi.** E. Rennerfelt. *Svensk botan. Tid.*, 1942, 36, 301-311 (through *Chem. Zentr.*, 1942, ii, 1194, and *Chem. Abstr.*, 1944, 38, 3469<sup>8</sup>). Mechanical wood pulp was inoculated with 20 different species of fungi. Only some, as *Fomes annosus*, *Lenzites betulina* and *Polyporus vaporarius* (Eberswalde), markedly attacked the wood pulp with a brown colouration and loss of weight of 19-25 per cent. Others, known as typical pests on dead conifers, such as *Lentinus lepideus* and *Lenzites abietina*, had scarcely any noticeable action on the pulp. If the entrance of the fungi is parallel to the pulp sheet, the action is greater than if it is perpendicular. Pulp from 8 different wood pulp plants showed variation of 12 up to 25 per cent. loss of weight upon inoculation with *Polyporus versicolor*; material put through a hydraulic press was attacked more rapidly than that which had been kamyr dried. C.

**Acetone: Micro-determination.** L. A. Greenberg and D. Lester. *J. Biol. Chem.*, 1944, 154, 177-190. A rapid, sensitive and accurate method for determining acetone in air and biological fluids is based upon the reaction of acetone with 2:4-dinitrophenylhydrazine to form the corresponding hydrazone, the separation of the hydrazone by extraction with carbon tetrachloride, and its colorimetric determination in this fluid. Applications of the method, and modifications, to the determination of total and individual ketone bodies (acetone, acetoacetic acid and  $\beta$ -hydroxybutyric acid) in blood and urine are also described. C.

**Alkanolamines: Volumetric Determination.** J. H. Jones. *J. Assoc. Offic. Agric. Chemists*, 1944, 27, 309-317. In a semi-micro volumetric method for the determination of alkanolamines in emulsions the amine is extracted with hydrochloric or hydrobromic acid, excess acid is removed by evaporation, and the amine is liberated by treatment with silver oxide, filtered and titrated with standard acid. The necessary correction for dissolved silver oxide is easily determined by titration with potassium iodide solution and starch-iodine indicator. When an inorganic base is also present the method may be used to determine the total base. Details of the procedure and typical results are given. C.

**2-Aminoanthraquinone: Determination and Identification.** O. L. Evenson. *J. Assoc. Offic. Agric. Chemists*, 1944, 27, 317-319. A colorimetric method for the determination of 2-aminoanthraquinone in D. & C. Blue No. 9 (3:3'-dichloroindanthrene) comprises removing the intermediate from the dye, treating with bromine to form 2-amino-1:3-dibromoanthraquinone and comparing the latter colorimetrically with standards. A 95 per cent. recovery is indicated. The preparation of 2-amino-1:3-dibromoanthraquinone and its acetyl derivative for identification of the intermediate is also described. C.

**Fats: Spectrophotometric Analysis.** B. W. Beadle and H. R. Kraybill. *J. Amer. Chem. Soc.*, 1944, 66, 1232. In the examination of animal fats containing small amounts of arachidonic acid by the method of Mitchell, Kraybill

and Zscheile, it is not possible to make a quantitative analysis for the arachidonic acid without a reference standard. Purified methyl arachidonate was therefore subjected to the alkali isomerization procedure and absorption coefficients were determined at or near the principal maxima, with a photo-electric spectrophotometer and ethanol as the solvent. Specific absorption coefficients at 2340, 2680, 3010 and 3160 Å. are given, together with coefficients at 2340 and 2680 determined with purified linolenic and linoleic acids. C.

**Hypochlorite Solutions: Oxygen Evolution.** P. Pierron. *Compt. rend.*, 1942, 215, 354-355 (through *Chem. Abstr.*, 1944, 38, 3210<sup>6</sup>). The evolution of oxygen in the dark from dilute and concentrated solutions of K, Na and Li hypochlorites at 20° and 100° was studied as a function of pH. Loss of oxygen due to evolution as gas and formation of chlorate increases with alkalinity and is greatest for the potassium and smallest for the lithium salt. In concentrated solutions decrease in pH is accompanied by decrease in loss of oxygen to a minimum at neutrality, followed by a second maximum with increased acidity. This behaviour can be explained by intermediate formation of peroxides; these can be detected. C.

**Barley Starch: Dextrinization.** K. Myrbäck and G. Stenlid. *Svensk Kem. Tid.*, 1942, 54, 103-115 (through *Chem. Zentr.*, 1943, i, 521 and *Chem. Abstr.*, 1944, 38, 3507<sup>1</sup>). The dextrinization of barley starch by amylase follows exactly the same course as previously reported for potato, corn and arrowroot starches, although these four starches differ in several respects and especially in their phosphorus content. The mechanism of starch hydrolysis is discussed. C.

**Corn Starch Linear Component: Fatty Acid Adsorption.** T. J. Schoch and C. B. Williams. *J. Amer. Chem. Soc.*, 1944, 66, 1232-1233. The adsorption of iodine by corn starch is markedly repressed by the presence of fatty acid. This effect appears to be due to preferential adsorption of fatty acid by the presumed linear component of the starch, viz., that component which is selectively precipitated by butanol and which is responsible for the blue colour with iodine. The higher fatty acids likewise act as selective precipitants for the linear-chain component of corn starch. By the treatment of a defatted corn starch paste with oleic acid the linear-chain fraction was separated as a microcrystalline floc in an amount equivalent to 29 per cent. of the original defatted corn starch. After prolonged Soxhlet extraction with methanol, its iodine affinity was 14.5 per cent. The non-precipitated fraction (presumably of branched molecular configuration) was isolated by treating the centrifugate with several volumes of methanol. After extraction with methanol, its iodine affinity was less than 0.2 per cent. Since traces of higher fatty acid will reduce the iodine adsorption, cereal starches must be exhaustively defatted before potentiometric evaluation of iodine affinity. The proportion of linear-chain component in corn starch can be determined approximately by dividing the iodine affinity of defatted corn starch by that of the repeatedly recrystallised butanol-precipitated fraction. This gives a calculated amount of 28 per cent. linear-chain component in corn starch, substantially higher than the amount previously reported by selective precipitation with butanol, but in excellent agreement with values more recently obtained by improved precipitation methods with certain of the amyl alcohols. C.

**Polysaccharides: Chemistry.** W. Z. Hassid. *Ann. Rev. Biochem.*, 1944, 13, 59-92. A review, with 110 citations, of work published during the past year or two on the structural chemistry of starch, glycogen, cellulose, the galactans, and other polysaccharides. C.

**Starch: Fine Structure.** P. Jaloveczky. *Bot. Közlemények*, 1942, 39, 601-619 (through *Schweiz. Brau. Rund.*, 1943, 54, Kart. der Brau.-Lit., 835/82, and *J. Inst. Brewing*, 1944, 50, 155-156). If dry potato- or canna starch granules are treated with a concentrated solution of ferric chloride, swelling starts at once, and is complete within 10 min. With nickelous chloride solution the action starts after 1 min., and is finished after 1 hour; with cobalt chloride solution swelling is first observed after 30 min., and whole granules can be seen on the following day. The finely-porous structure of the starch granule may be demonstrated by rapid penetration of the granule by iodine solution, followed by equally rapid decolorisation with sodium thiosulphate solution. If starch is treated with a 0.5 per cent. solution of potassium hydroxide it is possible to distinguish under

the microscope the small, clearly-defined nucleus; occasionally more than one is visible. A starch granule which has undergone a process of dry distillation develops an appreciably enlarged nucleus. Further details are given of the modifications in microscopic structure, optical properties and stratification effects which result from treatment with 1 per cent. sodium or potassium hydroxide solutions, ptyalin, 7.5 per cent. hydrochloric acid, zinc chloride solution, or from heat treatment, etc.; the appearance of the granules in polarized light is also discussed. The fine structure of the granules can also be rendered visible by treatment with dyes or with chromic acid, or, after heating in a bath of paraffin wax, with alcohol. C.

**Starch Substances: Acid Hydrolysis.** M. Samec and M. Dermelj. *Kolloid Z.*, 1942, 101, 123/126 (through *Chem. Zentr.*, 1943, i, 1274, and *Chem. Abstr.*, 1944, 38, 3507<sup>3</sup>). In the course of the acid hydrolysis of amyloamylose, erythroamylose and erythrogranulose changes in reducing power and optical activity are hardly discernible. Greater differences are observed by applying the unimolecular reaction constant to the rate of hydrolysis of maltose linkages in the maltose. C.

**Gelatin: Preparation.** W. M. Ames. *J. Soc. Chem. Ind.*, 1944, 63, 200-204. The work of various investigators on the preparation of gelatin and the influence of the type of precursor and method of extraction on the properties of the product is reviewed and a report is given of experimental studies of gelatins prepared from pigskin, sinews, ossein, and rabbit skin with different treatments. Time of extraction, yield, jelly strength, and iso-electric acidity and pH are tabulated. The data show that the gelatins fall into three groups, distinguished by the pH value at their iso-electric point, which does not depend on the type of precursor but on the pre-treatment before extraction. The iso-electric points were 6.0 for gelatin extracted with water, 8.9 for gelatin prepared by the acid process, and between 4.75 and 4.83 for the alkaline preparation. Use of acid, before or after a lime soak, did not appear to have any appreciable bearing on the extraction. All the gelatins, except those extracted with water, were of very good quality, as measured by capacity to form firm jellies. In further experiments gelatin was prepared from hide which had been soaked for different periods in milk of lime. It was found that gelatins could be prepared with iso-electric points gradually rising from an acidity of 0.24 per cent. to 1.4 per cent. or falling in pH from 6.0 to 4.77. The jelly strength and the time of extraction approximately followed the movement of the iso-electric point, the jelly strength gradually increasing and the time of extraction falling with falling pH. The yield of good gelatin also increased. These results afford an explanation of the variation in the position of the iso-electric point of commercial gelatins. In practice, extraction is carried out whenever the stage reached corresponds with good jelly strength irrespective of the position of the iso-electric point, which may fall anywhere between pH 6 and pH 4.77. C.

**Isinglass: Production.** F. G. S. Procter. *J. Inst. Brewing*, 1944, 50, 117-118. The effects of the war on the isinglass trade are discussed and the methods of preparing the different types are briefly described. C.

**Milk Casein: Composition.** G. A. Ramsdell and E. O. Whittier. *J. Biol. Chem.*, 1944, 154, 413-419. A procedure for determining the composition of casein as it exists in the caseinate-phosphate complex in milk is described which involves isolation of the complex by means of the supercentrifuge, its analysis, and calculation of the percentage content of the elements of the casein. Such a procedure avoids separation and alteration of the casein by chemical means and in consequence, prevents loss of P and S. Increase in alkalinity of the complex by the addition of neutral K oxalate indicated the presence of tricalcium phosphate rather than dicalcium phosphate in the complex. On this basis the complex was found to contain 4.80 per cent. calcium phosphate and 95.20 per cent. calcium caseinate. The latter fraction contained 1.18 per cent. Ca. A series of calcium caseinates was prepared from grain curd casein and the percentages of Ca were plotted against the pH of 3 per cent. dispersions prepared from them. The curve indicated that a caseinate of 1.18 per cent. Ca content would yield a pH of 6.40, which is only 0.07 pH more acid than the pH of the milk from which the complex was obtained. The results for the composition of casein obtained by this method check well, as a whole, with analyses of casein obtained by acid precipitation, thus indicating that the changes in physical

character through the action of acid are not accompanied by a pronounced alteration in its percentage elemental composition. C.

**Proteins and Amino Acids: Chemistry.** H. Neurath and J. P. Greenstein. *Ann. Rev. Biochem.*, 1944, **13**, 117-154. A review, with 261 citations, of recent work on (1) the preparation and identification of proteins, (2) protein hydrolysis, (3) isolation and determination of amino acids, (4) amino acid composition and distribution, (5) physical properties of proteins, (6) internal structure, and (7) denaturation. C.

**Silk Fibroin: Partial Hydrolysis.** W. H. Stein, S. Moore and M. Bergmann. *J. Biol. Chem.*, 1944, **154**, 191-201. The use of aromatic sulphonic acids as reagents for the isolation of peptides is discussed and approximate solubility products of arylsulphonates of several peptides and amino acids are tabulated. Data on the course of the hydrolysis of fibroin by concentrated hydrochloric acid at 40°, measured by nitrous acid and ninhydrin methods, are presented and discussed. The method of calculating the average peptide chain length at any given time during the hydrolysis is explained. From a partial hydrolysate containing dipeptides, glycyl-L-alanine and L-alanylglycine have been isolated by the successive use of 2:5-dibromobenzenesulphonic acid and 2:6-di-iodophenol-4-sulphonic acid. The amino acid composition of fibroin is discussed; several lines of evidence point to the probability that silk fibroin contains 30-35 per cent. of alanine. Preliminary analyses for L-tyrosine indicate a value of 11.9 per cent. C.

**Pectin Solutions: Viscosities.** H. S. Owens, H. Lotzkar, R. C. Merrill and M. Peterson. *J. Amer. Chem. Soc.*, 1944, **66**, 1178-1182. The relative viscosity of pectin solutions varies with concentration in a manner similar to that of other ionizable hydrophilic colloids and certain salts. The viscosity of dilute pectin solutions increases to a maximum as the pH is adjusted to a value near 6. The viscosity can be reduced to a minimum value by the addition of acid or sodium chloride. As the concentration of pectin is increased above 0.5 per cent., the relative viscosity is practically unaffected by changes in pH in the range of 1 to 7. Urea up to 0.5 molal concentration has little effect on the relative viscosity of pectin solutions. The relative viscosity/concentration curve follows the Arrhenius equation to a concentration of pectin of about 0.1 per cent. or more, depending upon the value for the intrinsic viscosity, when the solution is at pH 1-2 or when 0.9 per cent. or more of sodium chloride is present. This makes it possible to calculate values for the intrinsic viscosity which may have some relationship to the molecular weight. The viscosity/concentration curves for the pectinates of sodium, trimethylammonium, ethylenediammonium, 2:2-dihydroxymethylpropylammonium, and tetraethylammonium ions are practically identical. Changing the temperature from 0-50° has little influence on the relative viscosity of pectin solutions at concentrations below 0.05 per cent. Above that concentration the relative viscosity decreases with increase in temperature. Tentative explanations of these results are discussed. C.

**Macromolecules: Structural Analysis.** R. Lepsius. *Kunststoffe*, 1943, **33**, 133-138 (through *Chem. Abstr.*, 1944, **38**, 3183<sup>g</sup>). Physical methods of investigating the structure of high polymers are surveyed. Examples are given of the application of X-ray methods, Raman spectroscopy, ultra-microscopy, streaming birefringence, polarised light, electron microscopy, and ultrasonic waves. C.

**Oxidation-Reduction Potentials: Significance and Applications.** H. I. Stonehill. *J. Soc. Dyers & Col.*, 1944, **60**, 176-183. The significance of oxidation-reduction potentials is explained, methods of determining standard redox potentials are described, and applications to analysis, potentiometric redox titrations, redox indicators, the pH value of a redox solution, and miscellaneous applications of redox potentials are discussed. C.

**Hemicellulose: Photometric Determination.** C. J. Barton and A. J. Prutton. *Ind. Eng. Chem., Anal. Edn.*, 1944, **16**, 429-430. For the determination of hemicellulose dissolved in sodium hydroxide solution, K dichromate solution is added and the solution is acidified with concentrated sulphuric acid, boiled for about 30 sec. and then cooled. The transmittance at 600 mμ is measured and the hemicellulose concentration is determined from calibration curves based on iodometric determinations of hemicellulose concentration. Experimental details and transmittance curves are given. C.

**Physico-chemical Studies on the Water-soluble Fraction of Powdered Wool.** T. U. Marron and J. I. Routh. *Archives of Biochem.*, 1944, 4, 319-332. Aqueous extracts of wool which had been ground for varying lengths of time in a steel ball mill were studied with respect to the physical and chemical nature of the resulting soluble fraction. Precipitation data showed that only relatively few of the soluble particles were large enough to be precipitated by trichloroacetic acid. Tungstic acid removed less than half the biuret nitrogen from solution. The different fractions obtained on electrophoresis were characterised by variations in acidity, in biuret and tyrosine nitrogen content, and a change in response to the above protein precipitants. Polarographic studies indicated the heterogeneous nature of the soluble material. The polarographically active material accumulated in the electrophoresis cells at pH 3 and contained the major portion of the precipitable nitrogen. W.

**Wool: Structure and Reactivity.** A. Schöberl. *Forsch.-Ber. Zellwolle-u. Kunstseide-Rings*. G.m.b.H., 1941, No. 1, 283-287 (through *Chem. Zentr.*, 1942, II, 2327 and *Chem. Abs.*, 1944, 38, 3137). Wool of uniform grade contained cystine 10.78, dicarboxylic acids 28.98 and hexonic bases 15.62 per cent. by wt. As compared with the results of Elöd, Nowotny and Zahn (these *Abs.*, 1941, A601), wool treated for 8 days with water of 80° and mercury still contained 54 per cent. of the original cystine. The heavy metals are indicators for the hydrogen sulphide evolution from wool by the action of hot water. Wool can be coloured intensively and uniformly yellow by treatment at 80° with water containing cadmium. The fibre can be coloured black by means of metallic lead or iron. These metals are better than mercury for producing colour effects and form metallic sulphides more quickly on the surface of the fibre. Elöd, Nowotny and Zahn have not disproved the significance of sulphur for the strength and properties of the wool fibre. W.

## 10—ECONOMICS

**Chinese Textile Industries: Reconstruction.** Cha Chi-Min. *Textile World*, 1944, 94, No. 6, 85-87, 182-184. In 1937 the Chinese textile industry had 5 million spindles, 100,000 looms, and bleaching, dyeing, printing, finishing and knitting plant, all of modern types. About 60 per cent. of the spinning and weaving was under the sole control of Chinese people and the rest was almost all in Japanese hands. About 90 per cent. of the industry is now destroyed. Future prospects are reviewed and a Five-years Plan for rebuilding the industry with the help of American plant and money is discussed. C.

**Bombay Cotton Wages, 1914-1919 and 1939-1943.** *Indian Textile J.*, 1944, 54, 356-357. Available statistics are analysed in a comparison of cost of living and wage trends during the two World War periods. In both periods the great rise in costs occurred in the fourth year, but the operative is in a much better position now than in 1919, because wages and bonuses have not lagged so far behind. There have been much greater rises in the index for costs and wages in India than in England since 1942. C.

**Surat Weaving Industry: Organisation.** M. C. Munshi. *Indian Textile J.*, 1944, 54, 352-355. A brief history is given of the weaving industry of Surat from the early 16th century. In 1682 the export of cotton fabrics was 1,436,000 pieces. A characteristic feature in modern times is the large number of small establishments with about 3-5 power looms each. In 1942-43 a survey of 649 such places accounted for 4,108 looms, of which 3,645 were power looms, including many by Hattersley. The author discusses the reactions of this kind of establishment both on the hand-loom industry and on the large mills. C.

## 11—INDUSTRIAL WELFARE, INDUSTRIAL PSYCHOLOGY AND EDUCATION

**American Cotton Operatives: Employment on Three Shifts.** *Textile World*, 1944, 94, No. 6, 92-94. A number of opinions on working a third shift in American mills are reported. It appears to be general practice to use the third shift as a training ground for workers who are being prepared for promotion, but it is believed in many quarters that production would not suffer if the third shift were abandoned and the first and second shifts worked more efficiently. C.

**Cotton Spinners: Training.** Nell Woodward. *Cotton (U.S.)*, 1944, 108, No. 7, 89-91. An account is given of the experiences of an American university woman in learning the work of a spinner in order to train recruits. She emphasises (1) the bad tendency of old employees to discourage learners, and hence the value of using trained instructors, (2) the difficulty of imparting the names for machine parts and spinning products, and (3) the importance of persuading operatives to take adequate meals. C.

**Weaver's Wage: Calculation on Time-study Basis.** W. M. Fanning. *Textile World*, 1944, 94, No. 7, 51-55. The writer holds that wage incentives to increase production will be assisted if the wage system is based on accurate knowledge of the working conditions derived from time studies. The essential feature is to calculate the "standard minute" for a job, that is the amount of work done in one minute by the "standard operative." Thus, from observations of loom stops it is calculated that a weaver on looms running at 160 r.p.m. and 85 per cent. efficiency, should put in 0.31 standard-minutes per 1,000 picks. Her actual pick reading (from the clock) would then give her "standard time"; e.g. if she put in 2,077 picks in the 8-hour shift she would be credited with  $2077 \times 0.31 = 10.73$  hours. To this would be added compensation for loom idleness for which she was not responsible, say, 0.13 hour. At the basic rate of 63 cents her wage would then work out at  $(10.73 + 0.13) \times 63$  cents = 6.85 dollars. The same figure of 0.31 standard-minutes per 1,000 picks would also be used to calculate how many looms to assign to a weaver to give her the chance to earn more, say one-third more, that is to put in 80 standard-minutes per hour. Thus, supposing she runs looms at 160 r.p.m. and achieves an efficiency of 90 per cent. she would put in  $160 \times 60 \times 0.9 = 8.64$  thousand picks per loom-hour and could manage  $80 / (8.64 \times 0.31) = 30$  looms to secure one-third above the basic pay. Such reasoning is set out in detail for (a) "calculating a weaver's job," (b) battery-hand assignment and (c) the tackler's assignment. Thus, under (b) the job of replenishing bobbins is calculated to take 0.113 standard-minutes per bobbin, and under (c) the "standard minute" for loom tackling is 0.800 per loom-hour. C.

**Chlorovinyl Resins: Toxic Effects and Conditions of Use.** N. M. Pietropavlovsky. *Gigiena i Zdorov'e*, Moscow, 1942, No. 10, 14-20 (through *Bull. Hygiene*, 1944, 19, 450-451). It is believed that exposure for 3 minutes to an atmosphere containing 64 mg. of vinyl chloride causes in man giddiness, loss of orientation and headache, which lasts for about  $1\frac{1}{2}$  hours after return to the fresh air. White mice exposed to vapours from heated samples of vinyl resins containing about 53.7 per cent. chlorine showed (1) irritation of the visible mucous membranes, (2) hyperæmia of the extremities, ears and tails, (3) disturbances of coordination movements and disappearance of reflexes, (4) death from respiratory failure, sometimes with convulsions of the extremities and head. A post-mortem examination showed irritation of the respiratory tract, considerable oedema and necrosis of the tissues and degeneration in the liver, kidneys and heart. The main toxic substance was hydrochloric acid. To ensure hygienic conditions in the use of such resins it is essential that the decomposition temperature should be 20° higher than the maximum temperature reached in manufacturing processes. The heating of mixtures should be regulated by safety devices. A good local ventilation is essential. Medical supervision of all workers must be compulsory; personal hygiene must not be neglected. C.

**American Textile Schools: Organisation for Textile Research.** M. E. Campbell. *Amer. Dyes. Rept.*, 1944, 33, 313-315. Textile research in textile schools is discussed and it is pointed out that, although only a small proportion of the students will take up research work, a school should endeavour to acquaint all its students with the possibilities and limitations of the tools of textile research, with the most modern methods of analysing and interpreting the results of research, and with the identity, scope and objectives of the different organisations conducting textile research. An account is given of the staff, equipment, facilities and advantages for research of the Textile School at North Carolina State College. The two general types of research, fundamental and applied, are briefly discussed, and it is suggested that, in general, the greatest returns from research can be expected in a textile school if the programme centres around the application of principles to commercial production. The financing of research at a textile school is briefly discussed. C.

# ABSTRACTS—SUBJECT INDEX

## AIR CONDITIONING. See HUMIDIFICATION.

## ANIMAL NUTRITION. See SHEEP.

## ARTIFICIAL LEATHER.

Artificial Leather: Production. Brown Co.  
U.S.P.2,335,702 ... .. A347

## ASBESTOS.

Asbestos Friction Materials: Characteristics.  
R. T. Halstead ... .. A262  
Asbestos: Hygroscopic Behaviour; Influence in  
Organic Analysis. J. Lindner ... .. A485  
Asbestos Yarn: Impregnating with Synthetic  
Resin. American Cyanamid Co. B.P.  
563,678 ... .. A463

## BIO-CHEMISTRY.

Amylase: Activity. A. Janke ... .. A30  
Amylopectin: Synthesis. W. N. Haworth, S.  
Peat and E. J. Bourne ... .. A494  
Australian-grown Papain. W. J. Ellis and F.  
G. Lennox ... .. A86  
Cellulose: Aerobic Decomposition by Thermo-  
philic Bacteria. H. C. Murray ... .. A484  
Cellulose Bacteria: Activity. W. H. Fuller and  
A. G. Norman ... .. A271  
Cellulose-decomposing Bacteria: Action. R. Y.  
Stanier ... .. A490  
Cotton: Use as Culture Medium. E. J. Bottcher  
and H. J. Conn ... .. A490  
Enzymes: Constitution and Action. J. H.  
Quastel ... .. A31  
Malt Amylases: Stability and Separation. E.  
Kneen, R. M. Sandstedt and C. M.  
Hollenbeck ... .. A31  
Measuring Proteolytic Activity: Gelatin Viscosity  
Reduction Method. F. G. Lennox  
Protein and Cellulosic Rags: Use for Preparing  
Foodstuff. Sylvia M. Everett. B.P.  
558,889 ... .. A183  
Proteolytic Enzymes: Activity Measurement;  
Gelatin Viscosity Reduction Method.  
F. G. Lennox ... .. A271  
Starch: Amyolytic Degradation. W. N.  
Howarth, H. Kitchen and S. Peat ... .. A172  
Termite Protozoa: Digestion of Cellulose. R.  
E. Hungate ... .. A271  
Valine and Arginine: Microbiological Determina-  
tion. J. R. McMahan and E. E. Snell  
Waxy Maize Phosphorylase: Nature and Action.  
Laura Bliss ... .. A181

## BLEACHING.

### Materials, Methods and Control.

Alkali Metal Chlorites: Preparation. Mathieson  
Alkali Works, Inc. U.S.P.2,332,180,  
2,332,181 ... .. A276  
Alkali Metal Chlorites: Production. Mathieson  
Alkali Works. B.P.557,634 ... .. A86  
Animal Fibres: Bleaching with Hydrogen Peroxide.  
R. Sarg (to Elchemie G.m.b.H.).  
D.R.P.727,153 ... .. A251  
"Blankophor" White Fluorescing Substances:  
Application to Bleached Materials. R.  
Michel ... .. A295  
Bleaching Agents: Use in Laundries. A. Foulton  
Bleaching Agents and Dyehouse Chemicals:  
Safe Handling. United States National  
Safety Council ... .. A478  
Bleaching, Dyeing and Finishing: Developments  
Bleaching: Prevention of Fibre Damage. H.  
Baier and W. Hundt ... .. A93  
Bleaching Solutions: Analysis. C. F. F.  
Anadón ... .. A13  
Cautic Soda and Liquid Chlorine: Precautions  
in Handling. United States National  
Safety Council ... .. A59

Waterproofing without Rubber	A61	Cuprammonium Cellulose Spinning Solution: Preparation. Industrial Rayon Corporation. U.S.P.2,336,451	A379
Water-repellent Fabrics: Production. A. Chwala and A. Martina	A61	Cuprammonium Rayon: Production. J. Constant	A91
Water-repellent Finishes: Use of Wax Emulsions. J. V. Steidle	A300	Cuprammonium Rayon Steeping Lye: Repeated Use. A. B. Pakshver	A1
Water-repellent Textile Materials: Behaviour of Water Drops. A. Jarvann	A420	Cuprammonium Spinning Solutions: Regeneration. A. B. Pakshver	A4
<b>PULP. See RAYON, PAPER and WOOD.</b>		High-tensacity Viscose Rayon: Production. H. Fink and G. Plepp. (Vested in U.S. Alien Property Custodian.) U.S.P. 2,327,516	A92
<b>Raw Materials.</b>		Mineral Acid Solution of Cellulose: Spinning. H. Fink, G. Rath and R. Hofstadt. (Vested in U.S. Alien Property Custodian.) U.S.P.2,334,615	A285
Annual Plants: Pulping. R. Hornke	A46	Modified Regenerated Cellulose Fibres and Films: Production. E. I. Du Pont de Nemours & Co. B.P.562,184	A379
Cellulose Pulps: Sources and Preparation. W. Schieber	A331	Non-electrifiable Cellulosic Foil: Production. Hercules Powder Co. U.S.P.2,324,887	A91
Esterified Pulp Fibres: Effects on Paper. J. J. Harrison	A493	Paper Pulp: Reactivity during Xanthation. G. Jayme and Kuo-fu Chen	A333
Fibrous Pulp Liquid Treatment Apparatus. Thames Board Mills Ltd., M. H. Morley and H. N. Baker. B.P.559,909	A232	Polyalkylene Oxides: Application in Viscose Spinning. British Cellophane Ltd. B.P. 557,213	A48
Mechanical Wood Pulp: Attack by Fungi. E. Rennerfelt	A539	Rayon Cake Wrapping Device. Kirklees Ltd. and W. Tong. B.P.557,708	A46
Mechanical Pulps: Sodium Peroxide Bleaching. J. S. Reichart	A295	Rayon Cakes: High-frequency Drying. G. M. Clark (Radio Corporation of America). B.P.563,590	A457
Pulp: Production in France	A61	Rayon Continuous Spinning and Treating Apparatus. American Enka Corporation. U.S.P.2,334,825	A285
„ Specific Surface; Determination. Technical Association of the Pulp and Paper Industry	A25	Rayon Filaments and Fabrics: Production. E. Dersucher	A405
„ Viscosity Test in Cupriethylenediamine Solvent. E. P. Wood	A431	Rayon Incrustations: Prevention in Spinning. Industrial Rayon Corporation. U.S.P. 2,326,150	A92
Pulp and Paper: Treatment with Fungicides and Germicides. D. K. Ballmann and F. B. Smith	A3	Rayon Liquors: Filtration. A. Meyer	A456
Pulp-wood Holocellulose: Chain-length Distribution; Effect of Cooking and Bleaching. J. E. Atchison	A493	Rayon Spinning Bath: Control of Composition. A. Wehrung	A506
Raw and Bleached Groundwood Pulps: Differentiation. J. H. Graff	A348	Rayon Spinning Bath Recovery System; Use of Nickel Tubing	A46
Straw Pulps: Bleaching. S. I. Aronovsky, G. E. Nelson and E. C. Lathrop	A140	Rayon Spinning Solutions: Filtration. A. G. Arend	A46
Sniphite Pulp: Bleaching; Effect of pH. I. S. Khutorshchikov	A295	Stapled Rayon Yarn: Production from Continuous Filaments. J. Mackie & Sons Ltd. and J. P. Mackie. B.P.560,902	A235
Straw Pulp: Production. J. Eggert	A404	Strong Cellulose Acetate and Regenerated Cellulose Yarns: Production. H. Dreyfus. B.P.567,004	A6
Sulphite Pulps: Viscosity; Comparison of Cuprammonium and Cupriethylenediamine Measurements. A. J. Corey	A431		
Sulphite Waste Liquor: Ultrachromatographic Adsorption. G. A. Schröter	A449		
Sunflower Stalk Pulp: Production. K. H. Rauch	A231

## STANDARDISATION

### MEASUREMENT OF CLOTH THICKNESS

The importance of being able to measure the thickness of textile fabrics in a reliable manner has become increasingly evident as their application to, and design for service have been developed. It has also been apparent to those called upon to exercise such control that various engineers' instruments such as micrometer screw gauges and dial gauges may give widely different results on the same material. The discrepancies arise very largely from one source—the relative ease of compression of textile materials as compared with those of the mechanical engineer. It is therefore necessary to control carefully the pressure applied to the specimens to be tested for thickness. For this and other reasons arising from their peculiar properties, a standard method of measuring the thickness of textile fabrics is essential.

The present draft is not intended to provide a method applicable to all textile materials for all purposes. There are some constructions whose utility lies in possessing well defined thickness at low pressures. For these and other materials not sufficiently characterised by measurements within the pressure range of 1 to 10 lb. per sq. in., other methods and apparatus must be employed. There is, however, a very large bulk of cloths for which the present draft method is appropriate, including many of the wide range of mechanical and electrical fabrics.

Existing specifications and experience have provided the necessary information for this draft. It is therefore a conservative document. No special development work has been required, to arrive at any particular features, and it is confidently expected that there will be agreement between users of the method. It is important to observe that the method is essentially one for the laboratory. The gauge needs reasonably careful handling and the apparatus requires to be set up on a firm base so that the anvil is horizontal. This at once precludes its use as a portable pocket instrument. For works and other routine control purposes, where it may not be possible to use the apparatus described by this specification, secondary measuring devices will have to be used. These can, of course, be compared against the standard instrument for a given material. It may be that there is room also for a specification which will control the essential features of a thickness gauge for fabrics, which can be held in the hand, but the drafting committee favours the opinion that the adoption of the present proposal will be a sufficient advance for the present.

Explanations of some features of the instrument may be desirable. The choice of a dial gauge, rather than a micrometer screw gauge, is dictated by practical experience and the difficulty of obtaining concordant results with the latter type of instrument. Moreover, the pressure applied, even by ratchet type gauges, is actually high as well as variable; British practice (B.S.S.870) allows a range of  $1\frac{1}{4}$  to  $1\frac{3}{4}$  lb., which is equivalent to  $25\frac{1}{2}$  to  $37\frac{1}{2}$  lb. per sq. in.

The range of pressure 1 to 10 lb. per sq. in. over which it is intended that measurements shall be possible by this instrument, is determined by a variety of considerations. There is a lower limit to the pressure: the weight of the plunger assembly is such that the calculated pressure cannot be brought much below 1 lb. per sq. in. This is therefore a convenient minimum. The upper limit is decided by considerations of safety. The plunger and associated parts will sustain a considerable dead-weight load without appreciable distortion,

but it is essential that the load shall be truly axial and that no shocks be applied. The safe load, allowing for normal care in handling, should be well below the theoretically safe steady load, and it is considered that loading so as to give 10 lb. per sq. in. is a suitable maximum for ordinary purposes. Exceptionally, if special care is exercised, pressures of the order of 25 lb. per sq. in. may be used.

The choice of working pressure is to a large extent arbitrary. There are no over-riding considerations which would necessitate a single exact value for all fabrics for which this method of measurement is appropriate. This is reflected in the variety of pressures required by different extant specifications. Whilst it is considered to be desirable that the same pressure should be used for similar fabrics, the choice of pressure has been left to the material specification.

The task of the drafting committee was considerably lightened by the existence of B.S.S. No. 907 (1940) which deals with dial gauges for linear measurements. For general purposes the type described in Table No. 3 of that specification, having 40 or 50 divisions of 0.001 in. round a dial of  $1\frac{3}{4}$  in. to 2 in. diameter is considered suitable; but in exceptional cases the material specification may prescribe the more sensitive type having 100 divisions of 0.0001 in. round the dial.

It will be found that a variety of instrumental details do not appear in this draft. These are left to the discretion of the user and instrument maker. For example, the depth of throat may be less for a user concerned entirely with narrow fabrics. The form of the table surrounding and level with the anvil is a matter of individual convenience. To the instrument maker is left the form of the dead weights and the mode of setting them axially over the plunger: it is only necessary that they shall be readily seated and removed without jarring the gauge.

It is recognised that some care is required in the use of an instrument of this kind. Various proposals have been made to render the operation less subjective, such as the use of auxiliary gradual loading devices and standard lapse periods. It is considered, however, that the procedure laid down in the present draft will be adequate for all except a few materials, and special procedures for these can be prescribed as they arise.

## **TENTATIVE TEXTILE STANDARD No. 9, 1944**

### **METHOD OF MEASURING CLOTH THICKNESS**

**Under Loads of 1 to 10 lb. per sq. in.**

#### **Part I—The Instrument**

##### **General**

The instrument shall consist of a dial type gauge mounted vertically on a frame which is provided with an anvil below the foot of the gauge. The instrument shall also be provided with a table for supporting the fabric during thickness measurement. This shall consist of a smooth, plane, horizontal surface, surrounding the anvil and level with it, and of sufficient size to prevent any error in the measurement through bending of the specimen. The table may conveniently constitute part of the base of the frame.

##### **Specification**

(1) The gauge shall conform with the provisions of British Standard Specification No. 907—Class 1, except that the main return spring and back lug shall be omitted. It shall be fitted with a revolution counter, and rotatable bezel by means of which the instrument can be adjusted to read zero.

(2) Unless otherwise prescribed by the material specification, the gauge shall have 40 or 50 divisions of 0.001 in. round the dial. (See table No. 3 B.S.S. No. 907).

It is recommended that when a more sensitive type is considered to be necessary, the gauge shall have 100 divisions of 0.0001 in. round the dial. (See table No. 5 B.S.S. No. 907).

## *Method of Measuring Cloth Thickness—Part II*

(3) The gauge shall be provided with a foot having a hardened, polished, plane, circular face of  $0.375 \text{ in.} \pm 0.001 \text{ in.}$  diameter rigidly fixed to the plunger.

(4) The plunger shall have fixed axial deadweight loading such that the calculated pressure over the foot shall be  $1 \text{ lb. per sq. in.}$  when the dial reads zero. This requires a total deadweight of  $50.1 \text{ g. (0.110 lb.)}$ , including the plunger and foot, with a correction for the tension of the backlash spring.

For loadings which will give pressures greater than  $1 \text{ lb. per sq. in.}$  the loading shall continue to be axial.

This may be attained by any acceptable means, one satisfactory method being the provision of a platform. The platform shall form part of the fixed deadweight loading, and shall be rigidly fixed at the top of the plunger, and shall be provided with means for seating cylindrical weights which will increase the calculated pressure over the foot to a maximum of  $10 \text{ lb. per sq. in.}$

(5) The spring which is necessary to prevent backlash in the gauge shall not produce a change of pressure greater than  $0.1 \text{ lb. per sq. in.}$  (=load difference of  $5 \text{ g. or } 0.011 \text{ lb.}$ ) for a plunger movement of  $0.1 \text{ in.}$

(6) The gauge shall be fitted with a lever for raising and lowering the plunger so that contact with the material to be measured can be effected gently.

(7) The anvil shall be rigidly set in the frame and shall have a hardened, polished, plane, circular face of  $0.375 \text{ in.} \pm 0.001 \text{ in.}$  diameter.

(8) The surfaces of the foot of the gauge and anvil shall be co-axial and shall be parallel to within  $1/5000 \text{ in.}$  when tested by a feeler gauge at the edges.

(9) The gauge shall be rigidly fixed to an arm which shall be integral with the base of the frame.

(10) The plunger shall move perpendicularly to the face of the anvil.

(11) The rigidity of the frame shall be such that a load of  $1 \text{ lb.}$  applied to the dial housing, out of contact with the plunger, does not produce a deflection greater than  $0.0001 \text{ in.}$  as indicated on the micrometer dial.

## **Part II—Testing Technique**

### **Procedure**

(1) The instrument shall be set on a firm base so that the anvil is horizontal.

(2) The instrument shall be loaded so as to provide the pressure prescribed by the material specification.

(3) The surfaces of the anvil and foot shall be cleaned by placing a clean, smooth sheet of paper between them and withdrawing it, and the gauge shall then be made to read zero by the use of the adjustable bezel.

(4) The fabric shall be conditioned in the standard atmosphere (see B.S.S. No. 1051) in the loose state, for 24 hours, and the thickness measurement made under the same condition, unless contrary instructions are given in the material specification.

(5) The specimen of fabric shall be placed on the anvil in a single layer, flat and without tension. The foot of the gauge shall be lowered gently upon the fabric at a rate of about  $2/1000 \text{ in. per second}$ , and the reading taken immediately the easily visible movement of the pointer has ceased, unless contrary instructions are given.

### **Sampling and Numbering of Tests**

The number of samples to be tested and the manner of their selection shall be prescribed by the specification. In the absence of other instructions it is recommended that 10 places uniformly and randomly distributed over the specimen, but excluding selvages, shall be measured on any single specimen of material.

### **Criteria**

The material specification may prescribe the manner in which the results of the tests shall be examined; otherwise the mean value of the results shall be calculated.

## THE TESTING OF NARROW FABRICS

Towards the end of 1943 the Textile Institute received a request from the Narrow Fabrics Directorate of the Ministry of Supply for assistance in the preparation of recommendations for a series of standard testing methods, having particular reference to narrow fabrics. The wide range of application of narrow fabrics and the varied nature of their requirements had led to the existence of a great variety and multiplicity of methods of testing, and it was considered that the confusion and misunderstanding occurring in such circumstances could be avoided by the adoption of a system of unified methods of test.

The present proposals represent a step towards standardisation of testing methods for this class of materials. They are tentative recommendations, issued with the primary object of fulfilling practical war-time needs. The adoption of definite standards, for general peace-time purposes must necessarily be postponed until later deliberations of a more comprehensive and representative nature than have been attainable in present circumstances can be undertaken.

The recommendations have been prepared by a number of specialised technical committees appointed to deal with different groups of tests, and the decisions have been achieved largely through the medium of discussion, in the light of existing knowledge and experience. As was to be expected, however, in work of such extended scope, and in the present state of knowledge, investigations of a practical kind were necessary for several of the tests before a satisfactory procedure could be recommended. In the time available the experimental work has been necessarily limited, but it is considered that sufficient has been done to indicate the most suitable methods of test, and to make the range of tests comprehensive. It is left to the compilers of specifications to deal with any exceptional requirements and to prescribe modified or entirely different methods of test where necessary.

The tests are classified under four main types to facilitate reference. Part I comprises the general dimensional and physical properties. The tests have been drafted with special reference to narrow fabrics and certain recommendations are made with regard to details of apparatus and methods of testing which have been proved essential in practice. When the measurement of thickness was considered it seemed desirable to separate the description of the instrument and method of test from the main specification and accordingly Tentative Textile Standard No. 9, 1944, was drafted. The recommendations for machine capacity and rate of traverse in strength testing follow from the work of Technical Committee "A" of the Institute's Standardisation Scheme.<sup>1</sup> Methods of assessing bow and curl are given in order that these properties may be fully defined when necessary.

Part II contains a series of tests intended to provide a measure of the behaviour of elastic fabrics.<sup>2</sup> Methods of testing have been included which are designed to reproduce effects in the material approximating to those of actual conditions of use. This may be especially important in view of the impending greater use of synthetic rubber thread as a constituent of these fabrics. Notes on the issues involved in testing are inserted in the text where necessary.

Part III deals with chemical tests. For many of the tests in this section it has been necessary to include descriptive matter of greater length in order adequately to cover the testing operations, the apparatus and relevant issues. It is left to the material specification to prescribe the appropriate tests to be applied, also the manner of sampling the material, and the values by which the performance of bulk quantities of fabric shall be judged.

Part IV comprises the tests for colour fastness. The material specification should prescribe the appropriate tests to be applied where colour fastness is an important requirement of the fabric.

The majority of the tests, especially those in parts I and II have their texts arranged under one or more of a series of headings:—

## *Testing of Narrow Fabrics*

Under "General" the nature of the property to be assessed by the test is explained.

"Designation" covers the definition of the property to be measured by the test.

The "Units" by which the property shall be measured are also given where necessary.

Under "Testing Procedure" an outline is given of the practical operations, with attention to the arbitrary features of machines, technique and preparation of specimens.

In addition, it has been considered important to make some reference to other factors involved in the interpretation of the results of testing, and in the formation of representative judgments of fabric in bulk quantities. These can be considered under three headings:—

"Criteria" represents the choice of mean, maximum, minimum or range, etc., for the values given in the material specification; and the method of computing the results of testing for assessing their compliance with the specified values. The choice depends not only on the nature of the test but also on the intended use of the material.

Under the heading of "Performance" the material specification will usually prescribe the results to be shown by a satisfactory material in accordance with the given criteria. In appropriate instances, such as the mean of quantitative results, tolerances or limits should also be prescribed.

"Sampling and number of tests" includes the size of a sample and the manner of its selection from a consignment or other bulk quantity of material, the number of specimens to be tested from the material sample and the manner in which they should be taken. It is, of course, well known that the size and mode of selection of a sample should depend on the size of the bulk, on the variability of the material, on the kind of test and on the information which it is desired to obtain. For some tests it has not been found possible to give any guidance in this matter and it is left to the material specification to supply the necessary information. However, for some well established tests on certain types of materials, recommendations are made regarding the minimum size of a sample, and the number of tests to be carried out on such a sample, for a single determination of the property under test. This has been termed a unit sample. It is left to the specification to prescribe the relationship between the size of a consignment and the number of unit samples which should be tested. It will be noted that the recommended unit sample is of uniform size for certain groups of tests so that economy of material, time and labour is effected by using the same specimens for the various tests.

There is, of course, no question of prescribing a general method of sampling. The unit sample system would be less useful, for instance, in cases where the variation of a particular property may be identifiable, and where a scheme of sampling more closely related to the known causes of variation could be adopted; or in cases where certain characteristics were to be judged by high percentage inspection. The use of the unit sample system would be limited normally to ordinary cotton fabrics and those of similar variability and in the absence of other determining factors, though the scope of its application could be fairly extensive in narrow fabrics.

It is desirable that, when possible, all classes of testing of textile materials in bulk should be applied according to a design or plan broadly conforming to the principles of control outlined above. In the case of narrow fabrics this aspect of testing is of particular significance as variation of properties can be a relatively more serious matter than with most types of wider fabric.

Thanks are due to all who have contributed to the formulation of this series of tests; to the Society of Dyers and Colourists for its work in the preparation of the section on colour fastness; to the technical officers of Government Inspectorates; and particularly to the members of the eight technical sub-committees.

Acknowledgment is also due for the permission of the Textile Rot Proofing Panel of the Ministry of Supply to publish the tests in the chemical section dealing with iron, chromium, copper, zinc, manganese, paranitrophenol, Shirilan and pentachlorophenol. These tests are adapted from unpublished work carried out at the Shirley Institute and will form the subjects of future publications from that Institute.

Comments on the document or any part of it will be welcomed. They should be addressed to the Acting General Secretary, 16, St. Mary's Parsonage, Manchester, 3.

## Part I

### THE GENERAL DIMENSIONAL AND PHYSICAL PROPERTIES OF NARROW FABRICS

#### 1. CONDITION

##### Definition

The standard atmosphere for the conditioning of fabric samples for testing shall be as defined in British Standard Specification No. 1051, viz.:—

“ The conditions of an atmosphere at normal pressure denoted by a relative humidity of 65 per cent.  $\pm$  1 per cent. and a temperature of 70° F.  $\pm$  2° F.”

#### 2. DELIVERY CONDITION OF CONSIGNMENTS

##### General

The chief object in specifying the condition of fabric in the bulk consignment, when delivered, is that reasonable precautions shall be observed to ensure that no excessive amount of moisture is present in the fabric, as this might result in mildew and other forms of deterioration of the fabric during storage.

##### Testing Procedure

Samples of fabric taken from rolls selected from the consignment shall be weighed either immediately in the room where the goods are, or if this is inconvenient, they shall be transferred immediately to air-tight containers of known tare, which shall be weighed subsequently before the samples are removed for conditioning.

The samples shall then be conditioned in the standard atmosphere for 24 hours, and again weighed.

The accuracy of the weighing shall be of the order of 0.1 per cent. of the weight of the samples.

##### Sampling

The samples of fabric for this test shall be taken in such a manner that they are truly representative of the moisture condition of the consignment.

##### Performance

The material specification shall prescribe the maximum loss in weight as a result of conditioning.

In the absence of other determining considerations it is recommended that the loss in weight shall not exceed:

- 1 per cent. for materials composed of cotton, flax, acetate rayon, nylon, and other fibres having regains of similar order.
- 2 per cent. for materials composed of silk, hemp, wool, mohair, jute, viscose and cuprammonium rayons, and other fibres having regains of similar order.

#### 3. CONDITIONING AND PREPARATION OF SAMPLES FOR TESTING (Other than Delivery Condition)

##### (a) Fabrics (except elastic fabrics)

Specimens of fabric as required for the various tests, shall be prepared from samples which have been allowed to relax and condition in the standard atmosphere for 24 hours, and the tests shall then be carried out under the same condition.

If the specimens are required to be of definite length they shall then be marked to the requisite degree of accuracy with the aid of a steel rule.

In case of dispute and also when the samples lose more than the prescribed weight after conditioning as above, they shall first be dried in an atmosphere having a relative humidity of between 25 per cent. and 45 per cent., and a temperature not exceeding 40° C. (104° F.) and then re-conditioned in the standard atmosphere for 24 hours.

**(b) Yarns (except rubber thread)**

Packages of yarn (cheeses, hanks, etc.) from which specimens are to be taken for the purpose of any of the tests, shall be conditioned as described for fabrics in Method No. 3(a), unless contrary instructions are given in the specification.

Yarns extracted from fabric for the purpose of cloth analysis, etc., shall be taken from samples which have been conditioned and prepared as described in Method No. 3(a).

Yarns shall be measured after applying only just sufficient tension to remove crimp.

**4. TESTING OF FABRIC IN THE WET STATE**

It is recommended that wet tests shall be carried out only when the results so obtained are immediately relevant to the use of the material.

The conditions of wetting shall be so defined that reproducible results shall be obtainable.

**5. LENGTH****(a) Bulk Inspection**

The fabric shall be unrolled and drawn across a smooth, flat measuring table, preferably 5 yards long.

No more tension shall be applied to the fabric than is necessary to make it lie straight and flat.

The above procedure will normally be carried out under ordinary room conditions. In all cases of doubt or dispute the following method shall be employed:—

**(b) Testing**

The fabric shall be conditioned in the standard atmosphere, in the loose, unrolled state, for 24 hours, and the measurement, as described above, then conducted under the same condition.

**Sampling and Number of Tests**

A unit sample for either of the above methods shall consist of 5 rolls of fabric, and all shall be measured.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

**6. WEIGHT PER UNIT LENGTH****Units**

The weight per unit length shall be expressed in pounds and decimals of a pound, per gross yards.

**(a) Bulk Inspection**

The weight shall be taken of fabric which has been measured by Method No. 5(a) or (b), and the weight per gross yards calculated.

Alternatively the following method shall be used:—

**(b) Testing**

Short lengths of fabric shall be prepared from conditioned samples [see Method No. 3(a)] and these shall then be weighed to a suitable degree of accuracy, and the weight per gross yards calculated.

**Sampling and Number of Tests**

For the bulk inspection method a unit sample shall consist of 5 rolls of fabric and all shall be measured and weighed.

For testing, a unit sample shall consist of 5 lengths of two yards each; one from each of 5 rolls.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

## 7. WIDTH

### Units

The width of the fabric shall be measured in inches and fractions of an inch.

### (a) Bulk Inspection

The width shall be measured with a suitably graduated steel rule, and no more tension or pressure shall be applied to the fabric than is necessary to make it lie straight and flat.

The above procedure will normally be carried out under ordinary room conditions. In all cases of doubt or dispute the following method shall be employed:—

### (b) Testing

The fabric shall be conditioned in the standard atmosphere, in the loose, unrolled state, for 24 hours, and the width measurements then conducted under the same condition.

### Sampling, and Number of Tests

The material specification shall prescribe whether width measurement is to be carried out on the whole or a portion of the consignment, or on a unit sample, or number of unit samples.

In the absence of other determining considerations it is recommended that a unit sample shall consist of 5 rolls, and 5 measurements shall be made on each roll at randomly selected places.

### Criteria

The material specification shall prescribe whether the results shall conform to demands of maximum, minimum or mean width.

### Performance

The permissible limits of width shall be specified.

## 8. THICKNESS

### Units

Thickness shall be measured in mils. (Thousandths of an inch.)

### Testing Procedure

The fabric specimens for this test shall be conditioned and prepared as described in Method No. 3(a).

Thickness shall be measured by means of a dial micrometer. The construction of the instrument and the technique of the test shall be in accordance with Tentative Textile Standard No. 9.

### Sampling and Number of Tests

A unit sample shall consist of 5 lengths of 2 yards each; one from each of 5 rolls, and two measurements shall be made on each specimen.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

### Criteria

The material specification shall prescribe whether the results shall conform to demands of maximum, minimum or mean thickness.

### Pressure

The material specification shall prescribe the pressure under which the measurements are to be made.

### Performance

The permissible limits of thickness shall be specified.

## 9 (a). TENSILE STRENGTH—YARNS (SINGLE THREAD)

### Units

Breaking strength shall be specified in pounds and decimals of a pound.

**Testing**

The following conditions shall be observed:—

An approved testing machine shall be used with a working rate of traverse of 12 in. per minute.

The free length of a specimen at the start of a test shall be 20 in. between the grips of the machine.

The capacity of the machine shall be such that the specified figure for the breaking strength of the yarn under test is not less than 10 per cent. of the capacity of the machine.

All specimens for testing shall be conditioned in the standard atmosphere as described in Method No. 3(b), and the tests carried out under the same condition.

The yarn to be tested shall be taken from the fabric or package (cheese, hank, etc.) in such a manner that the twist in the yarn is not disturbed.

**Sampling and Number of Tests**

A unit sample shall consist of 5 packages (cheeses or hanks, etc.) and the number of tests from a unit sample shall be:—

50 for single yarns, 10 from each package.

20 for ply yarns, 4 from each package.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

**Criteria**

The specification shall prescribe whether the material shall conform to a mean, maximum, minimum or a range of strength.

**9 (b). TENSILE STRENGTH—FABRICS****Units**

Breaking strength shall be specified in pounds and decimals of a pound.

**Testing**

The following conditions shall be observed:—

The testing machine shall be:—

*either*: Constant rate of loading type, the rate of loading being such that the time taken to reach the specified breaking load shall be 1 minute.

*or*: Constant rate of traverse type, power driven, and with a uniform traverse speed of  $4\frac{1}{2}$  in. per minute.

The specification shall prescribe the type of machine to be used.

The free length of a specimen at the start of a test shall be 7 in. between the grips of the machine.

The capacity of the machine shall be such that the specified figure for the breaking strength of the material under test is not less than 10 per cent. of the capacity of the machine.

The specification shall prescribe whether the material is to be tested whole or whether specimens for testing are to be prepared from part widths. Narrow fabrics will normally be tested whole. When part widths are to be tested the specimens shall be frayed down to a width of 2 in. and the specification shall prescribe the width of fringe required to give satisfactory control of the edge threads in the tests.

All specimens for testing shall be conditioned in the standard atmosphere as described in Method No. 3(a), and the tests carried out under the same condition.

**Sampling and Number of Tests**

In the absence of other determining considerations a unit sample shall consist of specimens of fabric from 5 rolls, and the number of tests shall be 2 from each roll, giving a total of 10 tests. The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

**Criteria**

The specification shall prescribe whether the material shall conform to a mean, maximum, minimum or a range of strength.

**10. EXTENSION****Units**

Extension shall be expressed as a percentage of the length of the material before stretching.

**Testing Procedure**

Extension shall be measured after stretching the material in a tensile testing machine of the type specified for strength testing of yarns or fabrics.

The material specification shall state the initial and final loads between which the extension is to be measured. Whenever possible it is recommended that these shall be based upon the specified breaking load, or the specified weight per unit length of the material.

**Sampling**

The number of fabric specimens to be tested and the manner of their selection from the consignment shall be prescribed by the specification.

**11. SHRINKAGE****General**

Where satisfactory shrinkage performance is an important requirement of the material; the specification shall prescribe a suitable treatment and testing procedure, also sampling instructions and testing criteria.

**Units**

Shrinkage shall be expressed as a percentage of the length of the material before treatment.

**Measurement of Shrinkage**

The marking and measurement of the samples before and after the prescribed treatment for a shrinkage test, shall be as described in Method No. 3(a), the samples first having been conditioned in the standard atmosphere for 24 hours unless otherwise specified.

**12. FABRIC ANALYSIS—THREAD COUNTING****(a) Warp Ends**

The total number of ends in the width of the fabric shall be counted.

**(b) Picks, Plaits and Rows of Stitches**

Counting shall be on relaxed and conditioned short lengths of fabric prepared as described in Method No. 3(a). The countings must extend over at least a full inch, and to the nearest half thread, plait or row of stitches.

**Sampling and Number of Tests**

For warp ends, a unit sample shall consist of 5 rolls of fabric, and each shall be counted.

For picks, etc., a unit sample shall consist of specimens of fabric from each of 5 rolls, and two countings shall be made for each roll.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

**13. FABRIC ANALYSIS—YARN COUNT****General**

Because of the difficulty of dissecting many narrow fabrics it is recommended that the count of weft be determined by calculation from other tested cloth particulars as follows:—

The weight of warp in the fabric specimen is calculated from test results of total ends, warp crimp, warp count and specimen length. The weight of weft

is then obtained by difference from the weight of the fabric specimen. The length of weft is calculated from the tested picks per inch and the yarn length per pick. Then the weft count is computed from these calculated values of weight and length of weft.

#### **Preparation of Specimens**

Specimens of fabric  $2\frac{1}{4}$  yards long shall be conditioned as described in Method No. 3(a), and the subsequent dissection, measuring and weighing shall be carried out in the standard atmosphere.

##### **(a) Weight per unit length**

The weight per unit length of the fabric specimens shall be determined as in Method No. 6(b).

##### **(b) Number of threads**

The number of warp threads and picks shall be counted as in Method No. 12.

##### **(c) Measurement of pick length**

From each end of each  $2\frac{1}{4}$  yd. specimen ten picks of weft shall be dissected in a continuous length and measured under just sufficient tension to remove the crimp. The mean pick length for all specimens in the sample shall be calculated.

##### **(d) Measurement of warp crimp**

In each specimen two cuts shall be made a measured distance apart along the length of the fabric and two warp threads shall be dissected from this length and measured under just sufficient tension to remove the crimp. The warp crimp is the difference between the length of the warp threads and the distance between the cuts, expressed as a percentage of the distance between the cuts.

##### **(e) Warp count**

From the remainder of the  $2\frac{1}{4}$  yd. specimens, lengths of two yards are cut off and 10 complete warp ends are dissected from the full length of each 2 yd. specimen. These ends from all the specimens are then weighed together to an accuracy of 0.5 per cent., and the count is calculated after allowing for the mean warp crimp and any finishing treatment.

When the fabric is made from more than one beam or type of yarn the warp tests and calculations shall be repeated for each beam or type of yarn.

##### **(f) Weft count**

The weight of weft per gross yards of fabric is obtained by subtracting the weight of warp per gross yards [calculated by the test results of (b), (d) and (e)] from the fabric weight (a).

The length of weft per gross yards of fabric is calculated from the test results of (b) and (c).

The weft count is calculated from the length and corresponding weight so obtained.

#### **Sampling and Number of Tests**

A unit sample shall consist of 5 lengths of fabric, one from each of 5 rolls.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

## **14. TWIST IN YARNS**

### **Units**

The amount of twist shall be expressed as the number of turns per inch.

### **Testing Procedure**

The yarn to be tested shall be taken from the fabric or package (cheese or hank, etc.) in such a manner that the twist in the yarn is not disturbed.

The yarn shall be inserted in the testing apparatus with an amount of tension only just sufficient to pull it taut between the grips.

The yarn shall then be carefully untwisted and the point of zero twist deter-

mined by inserting a needle in the fibres and passing it from the fixed to the moving grip.

The following table gives recommended lengths of yarn for testing, and also the number of tests to be made from a unit sample:—

Single yarns. Cotton, Woollen, Staple fibre	} 1 in. or $\frac{1}{2}$ in.	50 tests.
Worsted, Mohair, Spun Silk, Hemp, Linen, Jute and similar material		
Continuous filament yarns	} 5 in.	20 tests.
Ply yarns. All types ... ..	10 in.	20 tests.

#### Sampling and Number of Tests

A unit sample shall consist of specimens from 5 packages of yarn, or from cuttings of fabric taken from 5 rolls. The number of tests on a unit sample shall be as indicated above.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

### 15. DIRECTION OF TWIST

"The direction of twist shall be as defined in British Standard Specification No. 946, viz.:—

#### Single Yarns

"A yarn has "S" twist if, when it is held in the vertical position, the spirals conform in direction of slope to the central portion of the letter "S". Similarly the yarn has "Z" twist if the spirals conform in direction of slope to the central portion of the letter "Z".

#### Folded Yarns and Cables

"The direction of the twist in successive twisting operations is described by a series of letters "S" and "Z" in which the first letter or group of letters gives the direction of the twist in the single yarns. The letter (or letters) referring to the single yarns, may, if desired, appear in smaller type.

"Twist in folded yarns is designated "S/S" or "Z/Z" when the folding turns are in the same direction as those in the single yarns.

"When folding twist is in the opposite direction to that in the single yarns, the designation is "S/Z" or "Z/S", and in successive cabling operations, yarns may be shown as "S/Z/S. . ." or "Z/S/Z. . ."

When single yarns of opposite twist are folded, the designations are "SZ/S" or "SZ/Z" according as the doubling twist is in the "S" or the "Z" direction."

### 16. CURL

#### General

The material specification shall prescribe whether the specimens shall be specially conditioned as described below, or otherwise pre-treated before their curls are assessed. If the conditions of use are such that unconstrained short lengths may develop or increase their curls by increase or fluctuation of moisture content, it is recommended that the specimens shall be exposed to water vapour or liquid water in such a manner as to effect such increase in the curl. For general purposes and in the absence of special considerations which indicate other procedure, it is recommended that the development method given should be adopted.

#### Preparation of Specimens

Fabrics wider than 2 in.:—Discs of 2 in. diameter shall be cut from the samples.

Fabrics narrower than 2 in.: Specimens 2 in. long shall be cut from the samples.

### Pre-Treatment of Specimens

The specimens shall be conditioned over a saturated solution of sodium sulphate in a closed chamber.\* If the air is not removed from the chamber the specimens shall be conditioned for 24 hours. If the air is very largely removed as by the use of a "desiccator" evacuated by water pump, the specimens shall be conditioned for one hour.

\*This solution gives approximately 82 per cent. R.H. at room temperature.

### Testing Procedure

The specimens shall finally be conditioned in the standard atmosphere for 24 hours, before proceeding to assess their curls.

In order to ensure the removal of transient curl they shall first be made to lie flat on a table; no more than the minimum pressure necessary for this purpose shall be employed and the specimens shall be held flat for 2 to 3 seconds.

The specimens shall then be allowed to curl freely for one minute.

Fig. 1.

The angular rotation of one extremity of the specimen with respect to the other is then assessed by viewing the curled specimen so that it presents the appearance of a cylindrical tube or part of such a tube. This will in general mean that the specimen is viewed along a line at some angle to the warp threads or weft. The assessment is made to the nearest 10 degrees. It has been found that when the curl is less than one whole turn the angle is more readily estimated when the specimen is held at arm's length so that the direction of one extremity is horizontal.

### Direction of Curl

If the direction of curl is important it is determined as follows:—

A line is drawn on the concave side of the specimen parallel to the axis of its cylindrical form. The angle between this line and the weft direction is measured, reckoning clockwise from the line.

If it is necessary, and possible, the face and back of the cloth shall be identified and the convexity or concavity of the face noted.

### Criteria and Performance

The material specification shall prescribe the desired performance in respect of curl and may include a demand that the direction of any particular curl shall be assessed.

### Sampling

The specification shall prescribe the number of tests to be carried out and the manner of their selection from the consignment.

## 17. BOW

### Preparation of Specimens

Samples of fabric exhibiting this characteristic shall be conditioned and prepared as described in Method No. 3(a). The fabric shall then be laid on a smooth surface without any constraint other than the application of such minimum pressure as is necessary to make it lie flat.

### Testing Procedure

A steel rule shall be placed on the fabric in such a manner that a chord of appropriate length spans the inside of a bowed portion of the fabric.\* The maximum perpendicular distance— $d$  inches—to this chord, from the edge of the fabric shall be measured with a second steel rule. The width of the fabric— $w$  inches—shall also be measured with a steel rule.

\*In view of the variability of this characteristic it is recommended that the length of the chord shall be relatively short. Therefore the chord length shall be 10 inches whenever possible, but in cases where the value of  $d$  is too small to be measured with reasonable accuracy, alternative chord lengths of 20 in., 30 in., or 40 in. shall be used.

### Expression of Results

The bow shall be expressed as the Percentage Length Differential, which is calculated from the formulæ:—

$$\begin{aligned} \text{Percentage Length Differential} = & \frac{8}{d} \frac{w}{w} \text{ for chord length of 10 in.} \\ & \frac{2}{d} \frac{w}{w} \text{ „ „ „ „ 20 in.} \\ & \frac{8}{9} \frac{d}{w} \text{ „ „ „ „ 30 in.} \\ & \frac{1}{2} \frac{d}{w} \text{ „ „ „ „ 40 in.} \end{aligned}$$

### Criteria and Performance

The material specification shall prescribe the performance of the material in this test, stating whether the specified value for bow relates to a maximum or a mean.

### Sampling

The specification shall prescribe whether inspection for bow is to be on the whole or a portion of the consignment and also the number of specimens to be tested.

## 18. WATER REPELLENCY—FABRICS

### General

This is a simple spray test in which the apparatus and practical operations are clearly defined so that reproducible results are assured. The results of testing are assessed after visual examination and comparison with an arbitrary scale of values ranging from maximum to minimum repellency.

### Apparatus

The spray device consists of a glass funnel fixed vertically, with a metal nozzle attached to the end of the stem by a short length of rubber tubing. The stem of the funnel is shortened to about  $\frac{3}{4}$  in. so that the face of the nozzle is 3 inches below the neck of the funnel.

The face of the nozzle is  $1\frac{1}{2}$  in. in diameter, slightly convex, and with 19 holes drilled with a No. 65 drill (0.035 in.). The perforations are equally distributed over the face of the nozzle, the arrangement comprising a central hole surrounded by two concentric rings of holes. The inner circle is of  $\frac{1}{2}$  in. diameter and contains 6 holes. The outer circle is of 1 in. diameter and contains 12 holes. The duration of flow for the test quantity of 250 ml. of water poured into the funnel should be 25-30 seconds and the spray should cover an area of 6 in. diameter at a distance of 6 in. from the nozzle.

The fabric test specimens are supported by clamping in a thin double frame of wood or metal—6 in. square inside dimensions. The fabric frame, when in position for a test, rests loosely on a suitable support so that it is at an angle

of 45 degrees to the stem of the funnel and with the centre of the test area 6 in. vertically below the centre of the spray nozzle.

### Testing Procedure

The specimens of fabric for this test (8 in. long) shall be conditioned in the standard atmosphere for 24 hours and the tests carried out immediately afterwards.

The minimum test width of fabric shall be 4 in.

For fabrics narrower than this two or more specimens shall be tested at one time, side by side, to give an effective width of 4 in. or over.

For fabrics wider than 6 in. strips at least 4 in. wide shall be prepared.

To carry out a test the conditioned fabric is mounted in the frame and placed in position below the spray nozzle. Unless contrary instructions are given, the fabric shall normally be placed so that the warp direction is parallel to the flow of water running off the fabric. 250 ml. of water at 70° F. shall then be poured into the funnel, this being done quickly, but steadily, in order that the spraying shall be continuous once it has commenced. Immediately the spray has ceased the fabric frame is removed and tapped smartly six times against a solid object (three taps each on opposite edges of the frame) to remove loosely adhering water from the face of the fabric. During this operation the fabric is held in an almost vertical position but with the test face leaning slightly forward.

Fig. 2. Apparatus for Water Repellency Test.

### Assessment of Results

The performance of the fabric in this test is judged by carefully examining the surface of the test specimen immediately after the test, while still in the clamping frame. The surface of the fabric is viewed by reflected light from both upward and downward directions. The extent of the actual wetting of the surface is noted and also the extent of penetration of the wetting below the surface of the fabric. A comparison is then made with a series of standard spray test ratings and the performance judged thereby. A suitable scale for such a series of standards would be in accordance with the following descriptions:—

- 100 Surface of fabric remains absolutely dry.
- 90 Slight random clinging of small droplets to surface.
- 80 Slight wetting of surface of fabric at points of impingement of the individual spray jets, not exceeding one-third of total surface area.
- 70 Considerable wetting of surface of fabric, exceeding one-third, but not covering the whole of the test area.
- 50 The entire surface of the fabric is wetted, but there is little or no penetration to the back.
- 0 Complete wetting and penetration throughout the test area.

Observation of the effect on the fabric during spraying, and also of the appearance of the globules of water remaining on the surface before subsequent tapping, will provide useful evidence in cases where there is some difficulty in classifying the result between two adjacent ratings in the scale.

Each determination shall be the average of 5 test results.

#### Criteria

The material specification shall prescribe the appropriate repellency standard for judging this test. In the absence of other determining factors it is recommended that this shall not be below the category of 90 in the above scale.

It is also recommended that wherever possible unproofed samples of the same fabric shall also be subjected to the test, and that the specification shall prescribe the minimum difference of repellency values between the proofed and unproofed fabric.

### 19. WATER REPELLENCY—YARNS

A small faggot weighing about 10 g. secured with thread at each end, shall be made up from the hanks and placed on the surface of distilled water contained in an open vessel. The water will previously have been heated to a temperature of 140° F. and this temperature shall be maintained throughout the test.

The yarn will be considered satisfactory if the faggot remains floating on the surface of the water for a period of 2 hours.

In case of doubt or dispute the yarn shall be conditioned before testing, as described in Method No. 3(b).

## Part II

### THE SPECIAL CHARACTERISTICS OF ELASTIC NARROW FABRICS

#### FOREWORD

In general, tests for the dimensional and physical properties of narrow fabrics, in Part I, shall also be applied as required, but the preparation of the samples for testing shall be as described in Method No. 20, with the single exception of the test for delivery condition which remains as in Method No. 2.

### 20. CONDITIONING AND PREPARATION OF SAMPLES FOR TESTING (Other than Delivery Condition)

#### General

Fabrics containing rubber threads continue to retract in length for a considerable time after manufacture, and it is therefore essential to ensure that samples for testing purposes shall be so treated as to bring about satisfactory relaxation before measurement.

#### Standard Atmosphere

This is defined in the first paragraph of Part I.

#### (a) Fabrics. (All tests except Determination of Weight per Unit Length)

Specimens of fabric as required for the various tests shall be prepared from samples which have been allowed to relax for not less than 4 days after taking

from the loom, or from the last finishing process or other source of substantial tension.

The samples shall then be warmed at a temperature of 90° F. for one hour, and shall then be "massaged" by stretching them twelve times to the point of greater resistance.

This treatment shall be followed by conditioning of the freely relaxed samples in the standard atmosphere for one hour.

If the specimens are required to be of definite length they shall then be marked to the requisite degree of accuracy with the aid of a steel rule, and for stretch measurements, a gauge distance shall be suitably marked.

**(b) Fabrics (Determination of Weight per Unit Length).**

The specimens of fabric shall be prepared as described above, but the time of final conditioning in the standard atmosphere shall be 24 hours.

**(c) Rubber Thread**

For tests involving measurement of the length of extracted rubber threads, e.g. determination of the unstretched length of the rubber threads in relation to the length in the fabric, or determination of count, the threads shall be withdrawn from 5 in. lengths of fabric prepared from samples which have been treated as described above in Method No. 20(a).

The extracted rubber threads shall be warmed at a temperature of 90° F. for a further period of one hour, and then again conditioned in the standard atmosphere for one hour.

## **21. RUBBER THREAD CONTENT OF ELASTIC FABRICS**

### **Designation**

The rubber thread content of elastic fabrics shall be specified as the total weight of rubber thread in a certain length of the finished fabric which has been relaxed and conditioned as described in Method No. 20(a).

### **Units**

The rubber thread content shall be expressed in pounds and decimals of a pound per gross yards of fabrics.

### **Testing Procedure**

Fabric specimens 5 in. long shall be prepared from samples which have been treated as described in Method No. 20(a).

From each specimen the same number of rubber threads shall be taken and the textile covering removed.

The rubber threads shall then be weighed to within an accuracy of 1 per cent., and from this weight and the knowledge of the total number of rubber threads in the whole width of the fabric the estimated mean weight of rubber per 144 yards shall be calculated.

### **Sampling and Number of Tests**

In the absence of other determining considerations, it is recommended that a unit sample shall consist of one specimen from each of 3 rolls of fabric, and that a total of 36 threads shall be extracted, 12 threads from each roll.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

### **Performance**

The material specification shall prescribe the permissible limits of rubber thread content of the fabric by this test.

## **22. STRETCH CHARACTERISTICS OF ELASTIC FABRICS**

### **General Remarks**

The performance of elastic fabrics can be considered under a number of headings, of which the following are the most important from the practical point of view of testing, and the satisfactory service of the material.

*The performance when the material is immediately stretched for periods not exceeding about 2 minutes.* The material should show an adequate limit of useful extension, and should develop an appropriate tension at this limit and at intermediate stretches both in extension and retraction.

*The behaviour when the material is stretched within the limit of useful extension for periods of the order of 18 hours.* Here it is a question of the imperfection of the elasticity or flow; a feature more to be expected in material containing synthetic rubber. The material should show a minimum decay of tension when stretched for such a period.

*The performance after periods of frequent stretching and relaxing within the limit of useful extension.* In such conditions resistance to fatigue is important; otherwise there may be serious loss of stretch characteristics, or even breakdown of the fabric due to actual failure of some or all of the rubber threads. Fabrics containing synthetic rubber are again more likely to be affected, and after such treatment it is essential that the elastic properties should be retained to a useful degree.

*The performance after much longer periods of time, of the order of 6 months and upwards.* Here it is a question of loss of the desired properties because of chemical changes in the rubber or other elastic constituent of the fabric. The material should show a minimum loss of elasticity when it is stored under certain defined atmospheric conditions.

The following tests in this section are based upon this classification.

## 23. IMMEDIATE ELASTIC PROPERTIES

### General

The following quantities are measured in this test: The stretch ratios  $S_1$ ,  $S_2$ ,  $S_3$ , etc., developed in the material when it is subjected to loads  $W_1$ ,  $W_2$ ,  $W_3$ , etc.

The material specification shall prescribe the loads to be applied, but the following recommendations are made:—

(1) The specification shall state the load required to stretch the material to its limit of useful extension or near thereto.

(2) In addition the specification shall prescribe, when considered necessary, certain loads intended to produce intermediate stretch ratios related to the use of the material, by either load-extension or unload-retraction, or both.

(3) The stretch ratio at zero load on completion of a test shall be measured.

### Designations

The *stretch ratio* is the ratio of the stretched length of the material to its original unstretched length.

The *Limit of Useful Extension*<sup>2</sup> is the same as the loom stretch or the stretch produced by the tension under which the fabric was woven, and it is the point at which considerably greater resistance is felt when the fabric is stretched between the hands. The method of determining its value is explained in the appendix to this test.

### Units

Loads shall be measured in pounds weight and decimals of a pound weight.

The stretch ratio shall be expressed decimally.

### Testing Procedure

Specimens of fabric for this test shall be prepared as described in Method No. 20(a). For measurements of stretch during the test a distance of 5 inches shall be suitably marked in the middle of each specimen, and the length of the specimens shall be such that when mounted in the testing apparatus there shall be a distance of 3 inches between each end of the marked length and the fixing points.

Loading and unloading shall be performed steadily, each weight being applied or removed gradually.

The load changes shall be effected successively at two minute intervals and the stretch measurements taken at the end of each interval.

Fabrics up to 2 in. wide shall be tested whole-width.

For fabrics wider than this the specimens shall be frayed down to a specified number of rubber ends occupying approximately 2 in.

#### Sampling and Number of Tests

In the absence of other determining considerations it is recommended that a unit sample shall consist of 3 rolls of fabric and that one specimen from each roll shall be tested.

The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

#### Criteria

The material specification shall prescribe whether mean values shall be computed or whether all the results shall comply with the performance demanded for the material or whether any other system of compliance of the results with the demands shall be followed.

#### Performance

The material specification shall prescribe the permissible limits of the stretch ratios which are to be measured by this test.

### APPENDIX

#### Determination of the Limit of Useful Extension

(1) Plot the characteristic curves of the fabric for load-extension and unload-retraction, on any convenient scale.

(2) Draw the tangent to the unload curve from the origin.

(3) Drop a perpendicular from any convenient point  $P_1$  on this tangent, to the load axis at A, and mark off on it a height AB equal to  $1/5$ th of the height  $AP_1$ .

(4) Draw a straight line through OB, and then draw a second tangent to the unload curve parallel to OB.

(5) Read off the extension at the point of contact  $P_2$  of the second tangent. This is the limit of useful extension. The load required to produce it is read from the load curve.

Fig. 3.

## 24. DECAY OF TENSION AT CONSTANT STRETCH-RATIO

### General

The decay of tension in this test is the fall of tension after a certain lapse of time during which a specimen of fabric has been maintained at a constant stretch-ratio. It is measured by the tension-ratio.

The material specification shall prescribe the stretch to be applied.

In the absence of other determining considerations it is recommended that the stretch-ratio for this test shall be the value given by the point of contact of the tangent from the origin to the unload curve.

### Designation

The tension-ratio is the ratio of the tension in the specimen at the end of the test, to the tension in the specimen at the start of the test.

### Units

The tension-ratio shall be expressed decimally.

### Preparation of Test Specimens

All samples of fabric for this test shall be treated as described in Method No. 20(a).

The material may be tested in the form of either bands or single strips. (see Note 1.)

Band specimens are formed from strips of fabric of suitable length by securing their ends together.

An appropriate gauge distance for stretch measurements shall be marked on all test specimens.

In the absence of contrary instructions it is recommended that band specimens shall be prepared from  $12\frac{1}{2}$  in. strips of fabric, by stitching the ends of each specimen together with a flat overlap of  $\frac{1}{2}$  in., using three rows of hand-sewn stitches. The loop so formed shall be laid flat with the overlap at one end, and marked with a gauge distance of 5 inches.

Specimens for testing in single strip form shall be 7 in. long unless otherwise prescribed and the gauge distance of 5 inches shall be marked centrally on each specimen.

Fabrics up to 2 in. wide shall be tested whole width.

For fabrics wider than 2 in., and in the absence of other deciding factors, it is recommended that the specimens shall be frayed down to a specified number of rubber ends occupying approximately 2 in.

### Apparatus

The apparatus shall comprise suitable means for maintaining the test specimens at any specified stretch-ratio, and for measuring the tension in the stretched specimens. The diagram illustrates a typical form of apparatus which has given satisfactory results in practical tests.

Band specimens are stretched by two brass bars of not greater than  $\frac{1}{4}$  in. diameter. The upper bar,  $b_1$ , is rigidly held by a brass boss,  $B_1$ , on a  $\frac{1}{2}$  in. mild steel rod  $R$ . The lower bar,  $b_2$ , is held by a brass shackle,  $S$ , having a lower aperture through which passes another brass bar of  $\frac{1}{4}$  in. diameter,  $b_3$ , held by an adjustable boss,  $B_2$ , on the rod  $R$ . The sides of the aperture have insulating cheeks of suitable material. The boss  $B_2$  is provided with a terminal,  $T$ , so that connection can be made to a 2-volt accumulator. Another wire has one end held in contact with the shackle by being bound under one of the knurled nuts which secure the bar  $b_4$  in the shackle. This wire is connected to the accumulator via a 2.5V flash lamp bulb and switch. With this arrangement it is possible to see whether the bar  $b_3$  is in contact with the bar  $b_4$ . It is necessary to keep the brass surfaces clean, otherwise the visual warning device may fail to operate. A hook,  $H$ , below the bottom plate of the shackle allows tension to be applied to the specimen by a hanger and deadweights and by a 1 kg. spring balance reading to 0.01 kg. When the tension so applied is just in excess of the tension in the specimen, the latter extends slightly and so breaks the contact between the bars. When stretched specimens are to be stored over-

night for the duration of the test, they can be removed by detaching the rod R assembly after removal of the hanger weights and spring balance. Further specimens can then be tested simultaneously by the use of additional rods and fittings. Strip specimens are tested by the use of suitable non-slip grips which slide on the bars  $b_1$  and  $b_2$ .

### Testing Procedure

When inserting test specimens in the apparatus single strips are fixed so that the gauge marks are clear of the grips; and band specimens are set so that the stitched overlap lies over one of the end supports. The tests shall be carried out under standard atmospheric conditions as described in Part I. Each specimen is brought to the required stretch-ratio, using the gauge marks for measurement, and the apparatus is then clamped in that position. The initial tension in the specimen is measured at the end of 2 minutes after applying the stretch. The specimen is then maintained in the stretched state for a period of 18 hours (see Note 2), after which the tension is again measured. The gauge distance is measured on the relaxed sample after a specified lapse of time, for comparison with the original length before the test.

NOTE 1.—It has been shown that there is no practical difference for the purposes of this test, in the results given by the two types of specimen.

NOTE 2.—Tension decay continues for a considerable time, if not indefinitely. In the absence of other decisive considerations it is recommended that 18 hours shall be specified for the duration of this test. This gives characteristic results and is also closely related to the conditions of use of many elastic materials.

### Sampling and Number of Tests

In the absence of other determining considerations it is recommended that a unit sample shall consist of three rolls and that one specimen from each roll shall be tested. The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

### Criteria

The material specification shall prescribe whether mean values shall be computed or whether all the results shall comply with the performance demanded for the material, or whether any other system of compliance of the results with the demands shall be followed.

### Performance

The material specification shall prescribe the permissible limits of the tension ratio of the material.

Fig. 4.

## 25. FATIGUE OF ELASTIC FABRICS

### General

Specimens of fabric are subjected to repeated stretching, after which the effects on the properties of the material are examined.

### Testing Procedure

Specimens of fabric for this test shall be prepared as described in Method No. 20(a).

The specimens shall first be mounted so that they are at zero tension, but not slack, and shall then be repeatedly stretched by suitable mechanical means

to the limit of useful extension, at a rate of 60 to 100 oscillations per minute, for a specified number of oscillations.

The specimens shall then be subjected to one or more of the following tests:

(1) Measurement of the length (over a previously marked portion), at zero tension, for comparison with the length before the fatigue treatment.

(2) Test for immediate elastic properties.

(3) Test for decay of tension.

The material specification shall prescribe the number of oscillations to be applied in this test, and shall prescribe the appropriate tests to be applied after the treatment.

#### **Sampling and Number of Tests**

In the absence of other determining considerations it is recommended that a unit sample shall consist of 3 rolls, and that a sufficient number of specimens shall be subjected to the fatigue treatment to enable each of the subsequent tests to be applied to one specimen from each of the 3 rolls. The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

#### **Criteria**

The material specification shall prescribe whether mean values are to be computed or whether all the results shall comply with the performance demanded for the material, or whether any other system of compliance of the results with the demands shall be followed.

#### **Performance**

The material specification shall prescribe the performance of the fabric in this test.

### **26. AGEING TEST**

#### **General**

Specimens of fabric are aged by a prescribed heating treatment in air, and are afterwards submitted to various tests to determine any deterioration in their properties.

#### **Ageing Treatment**

The fabric specimens for this test shall be prepared as described in Method No. 20(a).

The specimens shall then be heated in an electrically heated dark oven at a temperature of  $70^{\circ}\text{C.} \pm 1^{\circ}$  for 240 hours.

The total volume of the specimens shall not exceed 5 per cent. of the air space of the oven. The air shall circulate freely on both sides of the specimens; this may be achieved by a forced circulation of the air around suspended specimens, or by mounting the specimens on a cage which can be revolved in the oven. The oven shall be ventilated by devices dependent upon natural convection or by the deliberate introduction of a slow stream of fresh air equivalent to a complete change of air about three times per hour.

After removal from the oven the specimens shall be allowed to relax freely and condition for 24 hours in the standard atmosphere.

#### **Testing of Aged Specimens**

The material specification shall prescribe the tests to be carried out after the above treatment. One or more of the following tests may be prescribed:—

(1) Test for Immediate Elastic Properties. (2) Test for Tension Decay. (3) Fatigue Test. In addition, or alternatively, the following tensile test may be prescribed:—

The specimens shall be stretched in a tensile testing machine to the point of rupture of the textile warp threads. Such rupture shall take place in about one minute. The breaking load shall be observed and any breakage of the elastic threads at this point shall also be noted.

**Sampling and Number of Tests**

In the absence of other determining considerations it is recommended that a unit sample shall consist of 3 rolls and that sufficient specimens shall be aged to enable each of the subsequent tests to be applied to one specimen from each of the 3 rolls. The number of unit samples and the manner of their selection from the consignment shall be prescribed by the specification.

**Criteria**

The material specification shall prescribe whether mean values shall be computed or whether all the results shall comply with the performance demanded for the material, or whether any other system of compliance of the results with the demands shall be followed.

**Performance**

*Test of Immediate Elastic Properties and Test for Tension Decay at Constant Stretch-Ratio.* The performance shall be demanded in the form already described for those tests; the numerical values of the permissible limits will, however, require to be appropriately adjusted for the aged material.

*Tensile Test.* The material specification shall prescribe the permissible breaking load for the textile threads, and may demand that none of the elastic threads shall have broken under this load.

**27. APPLICATION OF ADDITIONAL TESTS TO ELASTIC FABRICS**

Any or all of the Chemical Tests and Colour Fastness Tests in Parts Three and Four of these proposals may be required by the material specification for an elastic fabric.

After such tests have been carried out, one or more of the following tests may be prescribed:—

- Test for Immediate Elastic Properties.
- Test for Tension Decay.
- Fatigue Test.
- Tensile Strength Test.

**Part III****CHEMICAL TESTS****28. pH VALUE OF AQUEOUS EXTRACT, ACIDITY AND ALKALINITY****Preparation of Extract**

10 g. of the sample, cut into pieces  $\frac{1}{2}$  in. square or less if practicable, shall be boiled in 200 ml. of distilled water for  $\frac{1}{2}$  hour. After decanting the extract, the fabric residue shall be twice re-extracted, each time with 100 ml. of distilled water for 15 minutes at the boil. The combined extracts shall be filtered, if necessary, and after cooling, made up to 400 ml. with boiled out distilled water.

**Testing for pH Value**

The pH value of the aqueous extract shall be determined by a standard method, either electrometrically, or by the use of appropriate indicators.

The material specification shall prescribe the appropriate pH range. Alternatively, in certain cases, the specification may prescribe a maximum permissible amount of acidity, calculated as sulphuric acid, or of alkalinity, calculated as sodium carbonate, determined by titration to a stated pH value. In such cases, titration may be either electrometric, to the stated pH value, or by the use of suitable or specified indicators.

**Blank Test on the Water**

This must be carried out under identical conditions and the necessary corrections applied.

## 29. TOTAL WATER-SOLUBLE MATTER

An aliquot portion of filtered extract prepared as described in Method No. 28, shall be evaporated to dryness on a steam bath. The residue shall then be dried to constant weight in an oven at a temperature of  $105^{\circ}$ - $110^{\circ}$  C., and its percentage weight in relation to the conditioned weight of the fabric calculated.

## 30. WATER-SOLUBLE CHLORIDES

### Method No. 1

10 ml. of extract prepared as described in Method No. 28, shall be transferred to a suitable vessel and a few drops of 2N-nitric acid are added.

A similar vessel containing a saturated solution of silver chloride in water to which a few drops of 2N-nitric acid and a few ml. of N-ammonium nitrate have been added, is connected to the first vessel by means of a suitable bridge. (See appendix.)

A stout silver wire electrode is placed in each vessel, and the cell so formed is connected in series with a tapping key and a galvanometer. N-100 silver nitrate is run into the extract solution, closing the circuit momentarily by means of the key, after each addition. The end point is indicated by a reversal of the galvanometer deflection.

### Appendix

A suitable bridge for use in the above test consists of a U tube of  $\frac{1}{4}$  in. glass tubing with legs about 2 ins. long. A solution of 3 per cent. agar in N-ammonium nitrate is allowed to set in the bend of the tube. Then the legs of the tube are filled with a solution of N-ammonium nitrate. The ends of the tube are plugged with rolls of filter paper.

Alternatively the following method may be employed:—

### Method No. 2

10 ml. of extract prepared as described in Method No. 28 shall be transferred to a 150 ml. beaker, diluted to 60 ml. with distilled water, and 1 ml. of 5 per cent. nitric acid added. Stir thoroughly and filter through a Whatman No. 42 paper into a 100 ml. Nessler tube, washing twice with distilled water. Make up to 100 ml. with distilled water and add 1 ml. of 0.1 per cent. aqueous solution of silver nitrate. Stir thoroughly and compare the turbidity with a series of standards prepared at the same time under similar conditions.

## 31. WATER-SOLUBLE SULPHATES

400 ml. of extract shall be prepared from 10 g. of the material as described in Method No. 28. The solution is filtered, and 3 ml. of concentrated hydrochloric acid are added. The solution is then brought to the boil and 10 ml. of a boiling 2 per cent. solution of barium chloride is added, drop by drop. The boiling shall be continued until the precipitate coagulates. Allow the mixture to cool overnight and weigh the barium sulphate in the usual manner.

## 32. WATER-SOLUBLE PHOSPHATES

### General

This is estimated as ammonium di-hydrogen phosphate volumetrically by titration with uranium acetate solution.

### Method

200 ml. of extract prepared as described in Method No. 28 shall be titrated with standard uranium acetate solution which is made up by dissolving 15 g. of uranium acetate in 500 ml. of water to which are added 17 ml. of glacial acetic acid.

1 ml. of uranium acetate solution  $\equiv 0.007$  g.  $(\text{NH}_4)_2\text{H}_2\text{PO}_4$

This is standardised against di-ammonium phosphate (A.R. quality) as follows:—

The uranium acetate solution is titrated into the extract solution until the end point is almost reached (pre-determined by a rough titration), then the solution is just raised to the boil and the titration completed. A 5 per cent. potassium ferro-cyanide solution is used as external indicator, the first brownish colouration being the end point.

### 33. EXTRACTION WITH OTHER SOLVENTS

#### General

The determination of matter extractable by the various organic solvents shall be carried out by the following standard method:—

#### Method

5 g. of the material shall be extracted for four hours in a Soxhlet extractor. The solution is then filtered, if necessary, and evaporated, and the residue dried to constant weight at a temperature of 105–110° C.

The method shall be applicable to any of the following solvents: ether, methylene chloride, alcohol, benzene-methyl alcohol mixture.

### 34. SOLUBLE CHROMIUM

#### Foreword

In those cases where proofing of fabrics against attack by micro-organisms is carried out by impregnation with chromium and iron salt solutions, followed by development with potassium chromate, the active proofing principle on the fibre is hexavalent chromium. The latter is estimated by the method described below for soluble chromium-hexavalent.

#### Extraction Procedure

A quantity of the material is well shredded. A portion (2.5 g.) is then weighed out into a 100 ml. conical flask, 50 ml. of extracting liquor are added (pH 7.8 borax/boric acid, for wool; pH 9.2 M20-borax for cotton and flax). The conical flask is weighed and the total weight noted. The contents of the flask are then maintained at 40° C. for 30 minutes with occasional shaking, then cooled, and any loss in weight by evaporation replaced by distilled water. The textile material is then removed by filtering through a Whatman No. 44 filter paper, and the chromium content of the solution determined.

#### (a) Soluble Chromium—Hexavalent

10 ml. of the filtrate are treated with 1 ml. of diphenylcarbazide reagent (an 0.2 per cent. solution in a mixture of glacial acetic acid—1 part, and rectified spirit—9 parts) followed by 2 ml. of 2N-sulphuric acid. The solution is made up to 50 ml. in a graduated flask. A standard chromium solution containing 0.00001 g. of Cr<sup>vi</sup> per ml. (0.0283 g. of K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> per litre) is prepared, and a set of colorimetric standards obtained by taking, respectively, 1, 2 and 3 ml. of this solution and treating after dilution with 1 ml. of the diphenylcarbazide reagent and 2 ml. of 2N-sulphuric acid. The volumes are then made up to 50 ml. in graduated flasks. After 15 minutes the solution prepared from the fabric and the nearest of the three standards are matched in a suitable colorimeter, using a depth of 30 mm. for the standard and varying the depth of the sample until the fields match. If the depth of the sample is less than 25 mm. or more than 35 mm. an adjustment must be made in the volume of the filtered extract taken. The volume of the extract in ml. to be taken in the final matching will be 10 × depth of sample / depth of standard. Assuming that a 2 ml. chromium standard has been employed to match the colour generated from 10 ml. of the cloth extract solution, the result in p.p.m. of Cr<sup>vi</sup> on the air-dry weight of the fabric is calculated as follows:—

$$\text{Cr}^{\text{vi}} \text{ p.p.m.} = 0.00002 \times \frac{\text{depth of standard}}{\text{depth of sample}} \times \frac{50}{10} \times \frac{10^6}{2.5}$$

**(b) Total Soluble Chromium**

A volume of the filtrate equal to that finally taken in the previous determination is treated with 0.5 ml. of water saturated with bromine and then with 2N-sodium hydroxide until the colour has discharged and two drops have been added in excess. After 1 minute, 1 ml. of an 0.7 per cent. solution of phenol, 1 ml. of the diphenylcarbazide reagent, and 2 ml. of 2N-sulphuric acid are added. The volume is then made up to 50 ml. with distilled water. After 15 minutes, the colour is matched against the standards as already described.

### 35. IRON, CHROMIUM, COPPER—PRELIMINARY SEPARATION METHODS

**General**

The methods for the analysis of fabrics containing iron, chromium and/or copper depend upon the number of metals in the material and the quantities in which they are present. The separation of the constituents to be determined usually presents more difficulty than their estimation and it has therefore been deemed advisable to give the procedure in some detail. The following methods of analysis will cover the majority of cases, but instances may arise of difficulty in the dissolution of metals after the preliminary ashing or of difficulties introduced by the presence of silica (e.g. from china clay in sizing) or of metals other than those listed. It is desirable, therefore, that all analyses should be carried out by, or under the direction of an experienced analyst.

**(a) Copper content large; iron and chromium absent**

The material (5 g.) is dried at 110° C., weighed, transferred to a 55 mm. silica or porcelain crucible and ashed in a muffle furnace at incipient red heat (450° C.). The ash is dissolved by heating with 2N-sulphuric acid, the solution transferred to a conical flask, filtering if necessary, and the copper determined by Method No. 38(a).

**(b) Copper content small; iron and chromium absent**

The sampled material (1 or 2 g.) is dried at 110° C., weighed and ashed in a silica or porcelain crucible at incipient red heat. The ash is digested with aqua regia, the solution evaporated to dryness, the residue moistened with a few drops of 0.2N-hydrochloric acid, and evaporated again. It is then dissolved in 0.2N-hydrochloric acid, filtered if necessary, and made up to 100 ml. Copper is then determined by Method No. 38(b).

**(c) Iron present; copper and chromium absent**

The sampled material (1 or 2 g.) is dried at 110° C., weighed and ashed in a silica or porcelain crucible at dull red heat. The ash is digested with 5 ml. of concentrated hydrochloric acid until the ferric oxide has dissolved completely, and the solution evaporated to dryness. The residue is dissolved in N-hydrochloric acid and transferred to a 250 ml. conical flask, filtering if necessary. If the iron content is large it is determined by Method No. 36(a). If the iron content is small, the filtrate is made up to 100 ml. in a graduated flask and the iron determined by Method No. 36(b).

**(d) Chromium present; iron and copper absent**

The sampled material (1 or 2 g.) is dried at 110° C., weighed and ashed in a silica or porcelain crucible at dull red heat. The ash is digested with concentrated nitric acid (5 ml.) and A.R. potassium chlorate (0.3 g.), the crucible being covered with a watch-glass during the process. After the chromic oxide has dissolved, the contents of the crucible are evaporated to dryness, treated with 5 ml. of 2N-sulphuric acid and evaporated to dryness again. The residue is then treated with 2N-sulphuric acid and transferred to a 250 ml. conical flask, filtering if necessary. If the chromium content is large it is determined by Method No. 37(a). If the chromium content is small, the solution is made up to 100 or 250 ml. and analysed by Method No. 37(b).

**(e) Iron and chromium present; copper absent**

The sampled material (1 or 2 g.) is dried at 110° C., weighed and ashed in a muffle furnace at dull red heat in a 55 mm. silica or porcelain crucible. Concentrated nitric acid (5 ml.) and potassium chlorate A.R. (0.3 g.) are added and the crucible is heated on a boiling water bath until a clear solution or one containing only a white residue of silica is obtained. After evaporation to dryness the residue is dissolved in dilute sulphuric acid (5 ml.) and the solution again evaporated to dryness. The residue is then dissolved in dilute sulphuric acid and transferred to a 250 ml. conical flask, filtering to remove silica if necessary. The filtrate is brought to the boil and sufficient 2N-sodium hydroxide is added to precipitate the iron as ferric hydroxide and afford an excess of approximately 10 ml. The flask is then closed with a pear bulb stopper and the solution boiled for one minute before filtering through a No. 541 Whatman filter paper. The filtrate containing the chromium as sodium chromate, is acidified with sulphuric acid and analysed by Method No. 37(a) or (b), according to the quantity present. If Method (b) is used the acidified solution is cooled and made up to 250 ml. in a graduated flask.

The ferric hydroxide precipitate is dissolved in hot N-hydrochloric acid and the solution cooled. If the amount of iron is large it is estimated by Method No. 36(a). If the iron content is small the solution is made up to 250 ml. and Method No. 36(b) employed.

**(f) Copper and chromium present; iron absent**

The sampled material (1 to 5 g. according to the anticipated copper and chromium contents) is dried at 110° C., weighed and ashed in a muffle furnace at incipient red heat in a silica or porcelain crucible. Concentrated nitric acid (5 ml.) and A.R. potassium chlorate (0.3 g.) are added and the crucible is covered with a watch-glass and heated on a boiling water bath until solution is complete except for any silica which may be present. The solution is evaporated to dryness, 1 ml. of concentrated hydrochloric acid is added, and the solution again evaporated to dryness. The residue is then treated with 0.2N-hydrochloric acid and the solution transferred to a 60 ml. beaker, filtering through a No. 44 Whatman filter paper if necessary. The copper is then precipitated with hydrogen sulphide in the cold and, after heating on the water bath, the gas is passed into the solution again to ensure complete precipitation: the supply is then disconnected leaving the glass tube in the beaker. The copper sulphide is filtered off through a No. 44 paper and well washed with distilled water saturated with hydrogen sulphide. Traces of copper sulphide adhering to the beaker and tube are dissolved in 2 ml. of aqua regia and the beaker is heated on the water bath until effervescence ceases. The solution is then transferred to the crucible in which the filter paper containing the copper sulphide has been ashed. The beaker and tube are washed with 1 ml. portions of aqua regia, which are transferred to the crucible, the combined solution being evaporated to dryness. If the amount of copper is large the residue is dissolved in 2N-sulphuric acid, the solution transferred to a 250 ml. conical flask, filtering if necessary, and the copper is determined by Method No. 38(a). If the quantity of copper sulphide is only small the residue is taken up in 0.2N-hydrochloric acid and the solution is transferred to a 100 ml. or 250 ml. graduated flask, filtering if necessary through a No. 44 Whatman paper. The copper is then determined by Method No. 38(b).

The filtrate from the copper sulphide, containing the chromium is boiled in a conical flask closed with a pear bulb stopper until free from hydrogen sulphide. The solution is then cooled and treated successively with 100 volume hydrogen peroxide (3 ml.) and an excess of 2N-sodium hydroxide. It is then heated on a water bath until effervescence has subsided, 5 ml. of a 5 per cent. solution of nickel sulphate are added and the solution is boiled for 5 minutes, cooled and acidified with concentrated sulphuric acid (10 ml.). Chromium is then determined by Method No. 37(a).

If the quantity of chromium is small, the solution which has been boiled to remove hydrogen sulphide is cooled, acidified with 2N-sulphuric acid and made up to 250 ml. in a graduated flask. The chromium is then determined by Method No. 37(b).

**(g) Iron and copper present; chromium absent**

The sampled material (1 or 2 g.) is dried at 110° C., weighed and ashed in a muffle furnace at incipient red heat in a silica or porcelain crucible. The ash is dissolved in aqua regia, and when effervescence has ceased, the watch-glass cover is removed and the solution evaporated to dryness. The residue is dissolved in 0.2N-hydrochloric acid and the solution transferred to a 60 ml. beaker filtering if necessary. Copper is then precipitated and separated as described in Method No. 35(f).

The filtrate from the copper sulphide is boiled until free from hydrogen sulphide, the mouth of the 250 ml. conical flask being closed with a pear bulb stopper. The solution is made approximately N in hydrochloric acid and the iron determined by Method No. 36(a) if it is present in quantity. If only traces are present, the solution is cooled and made up to 100 ml. or 250 ml. in a graduated flask. The iron is then determined by Method No. 36(b).

**(h) Iron copper and chromium all present**

The sampled material (1 or 2 g. according to the anticipated content of metallic oxides) is dried at 110° C., weighed and ashed in a muffle furnace at incipient red heat. The ash is dissolved by warming with a mixture of concentrated nitric acid (5 ml.) and A.R. potassium chlorate (0.3 g.) and the solution evaporated to dryness. The residue is treated with concentrated hydrochloric acid (1 ml.) and the solution evaporated to dryness again. The residue is dissolved in 0.2N-hydrochloric acid and, after filtering off any silica that may be present, copper is separated and determined as described in Method No. 35(f).

The filtrate from the copper sulphide, contained in a conical flask closed with a pear bulb stopper, is boiled until free from hydrogen sulphide. 100-volume hydrogen peroxide (3 ml.) and an excess of 2N-sodium hydroxide are added and the flask is heated on a water bath until effervescence has subsided. The precipitated ferric hydroxide is filtered off, washed with boiling distilled water, and redissolved in hot N-hydrochloric acid. If the iron content is large, this solution is analysed by Method No. 36(a). If the iron content is small, the solution is cooled and made up to 250 ml. in a graduated flask before analysis by Method No. 36(b).

The filtrate containing the chromium as sodium chromate is acidified with 2N-sulphuric acid and, if the content is small, it is made up to 250 ml. in a graduated flask and determined by Method No. 37(b). If the chromium content is large, the solution is treated with a 5 per cent. solution of nickel sulphate (5 ml.), boiled for 5 minutes, cooled, acidified with concentrated sulphuric acid (10 ml.) and the chromium determined by Method No. 37(a).

## 36. IRON

### (a) Macro-method

The solution of iron in N-hydrochloric acid is passed through a silver reductor\* and collected in a 600 ml. conical flask. The reductor is washed with 150 ml. of N-hydrochloric acid and the combined filtrate and washings titrated with 0.2N-ceric sulphate using 0.5 ml. of 0.02M-orthophenanthroline-ferrous sulphate as indicator.

The indicator is prepared by dissolving 0.3 g. of o-phenanthroline and 0.14 g. of ferrous sulphate in 250 ml. of water.

A blank titration is made on 150 ml. of the N-hydrochloric acid after passing through the reductor and any necessary corrections applied.

---

\*Walden, Hammett and Edmonds. *J. Amer. Chem. Soc.*, 1934, 56, 350.

**(b) Micro-method**

An aliquot part of the iron solution is diluted to 45 ml. with distilled water in a 50 ml. measuring flask, treated with 3 drops of thioglycollic acid, and the solution mixed thoroughly. Ammonium hydroxide (2 ml.) is then added and the volume adjusted to 50 ml. A suitable depth of shade for colorimetric comparison is given by a solution containing 0.0001 g. of iron in 50 ml. The amount of the test solution to be used for the final matching should therefore be determined by preliminary comparisons with a solution prepared in this way. The comparison is made in a suitable colorimeter with the standard at a depth of 30 mm.

**37. CHROMIUM****(a) Macro-method**

The sodium dichromate solution is titrated with 0.1N-ferrous ammonium sulphate using phenylanthranilic acid as indicator.

1 ml. of 0.1N-ferrous ammonium sulphate  $\equiv$  0.002534 g.  $\text{Cr}_2\text{O}_3$   
 $\equiv$  0.001733 g. Cr

The indicator is prepared by dissolving 1.065 g. of phenylanthranilic acid in hot water containing 0.53 g. of A.R. sodium carbonate, and diluting to 1,000 ml.

**(b) Micro-method**

A suitable aliquot part of the dilute chromium solution is transferred to a 50 ml. graduated flask, diluted to 40 ml. and treated with 1 ml. of saturated bromine water. 2N-sodium hydroxide is then added drop by drop, until the yellow colour disappears and there are two drops in excess. After 1 minute 1 ml. of 0.68 per cent. phenol, 1 ml. of 0.2 per cent. diphenylcarbazine (in a mixture of acetic acid 10 per cent. and rectified spirits 90 per cent.) and 2 ml. of 2N-sulphuric acid are added in this order. The volume is adjusted to 50 ml. and after mixing thoroughly, the solution is matched against standards prepared from a chromium solution containing 0.00001 g. of chromium per ml. A depth of shade suitable for matching in the colorimeter is obtained with 2 ml. of standard chromium solution treated in the above manner and diluted to 50 ml. If possible, the volume of the test solution used should be adjusted by preliminary trials to give a depth of shade close to the standard. Should this be impossible a 1 ml. standard must be employed.

**38. COPPER****(a) Macro-method\***

Potassium iodide (2 to 3 g.) is added to the solution of copper in 2N-sulphuric acid. After 5 minutes it is diluted with distilled water and the liberated iodine titrated with 0.1N-sodium thiosulphate until the colour has almost disappeared. A few drops of a freshly prepared solution of soluble starch are then added and the titration continued until the solution is nearly, but not quite colourless. Ammonium thiocyanate (2 g.) is then dissolved in the solution and the titration continued until the blue colour disappears completely.

1 ml. of 0.1N-sodium thiosulphate  $\equiv$  0.006357 g. of copper.

If only a small amount of yarn or fabric is available or the copper content is low, 0.01N-sodium thiosulphate may be used instead. If this is done it is preferable to add the ammonium thiocyanate at the beginning of the titration.

**(b) Micro-Method**

A suitable aliquot part of the dilute copper solution is transferred to a 50 ml. measuring flask and treated successively with 10 ml. of a 4 per cent. solution of sodium pyrophosphate, 5 ml. of a freshly prepared 1 per cent. solution of gum arabic, 1 ml. of a 0.2 per cent. solution of sodium diethyldithiocarbamate and 1 ml. of 0.880 ammonia before making up to volume. The colour of the solution is matched against standards prepared similarly from a copper solution

\*Foote and Vance. *J. Amer. Chem. Soc.*, 1935, 57, 445.

containing 0.00001 g. of copper per ml. in a suitable colorimeter, a 10 ml. copper standard at a depth of 30 mm. giving a suitable average colour density.

### 39. MANGANESE

(a) **Manganese in presence of copper; no other metals being present in appreciable amount.** (Materials intended for rubber proofing).

The sampled material (10 g.) is dried at 110° C., weighed, transferred to a large crucible or silica dish and ashed at incipient red heat in a muffle furnace. The ash is dissolved in aqua regia, the solution evaporated to dryness and transferred to a small beaker with 0.2N-hydrochloric acid. Hydrogen sulphide is then passed into the solution first in the cold and again after boiling and the precipitate filtered off using a No. 44 Whatman filter paper. After washing with distilled water saturated with hydrogen sulphide, the paper is dried, ashed in a porcelain crucible and treated with a small quantity of aqua regia which has been previously used to wash the beaker and the tube used in the precipitation. After evaporation to dryness the residue is taken up in 0.2N-hydrochloric acid and the solution transferred to a graduated flask (50 ml. or 100 ml. according to the anticipated copper content) and the copper determined by Method No. 38(b).

The filtrate and washings from the precipitation of copper sulphide are evaporated to dryness, moistened with concentrated sulphuric acid and a few drops of concentrated nitric acid, and heated cautiously over a flame until fuming is observed. The residue is diluted with distilled water and transferred, filtering if necessary, into a conical flask (100 ml.), the volume being adjusted to about 30 ml. Concentrated sulphuric acid (8 ml.) and potassium periodate (0.3 g.) are then added and the solution is boiled for about 1 minute and then heated for 15 minutes on a steam bath. After cooling, the solution is made up to a definite volume according to its colour and compared in a colorimeter with a suitable standard prepared by oxidation of a standard solution of manganese under similar conditions.

To prepare a standard solution of manganese, potassium permanganate (0.2877 g.) equivalent to 0.1 g. manganese, is dissolved in 300 ml. of water, the solution being acidified with 2N-sulphuric acid (2 ml.) and treated with sulphur dioxide until decolourised completely. The excess of sulphur dioxide is then removed by boiling and the solution cooled and diluted to 1 litre. This solution is finally diluted tenfold, so that the final manganese content is 0.00001 g. per ml.

(b) **Manganese in presence of iron, chromium, copper**

Method No. 35(h) is followed up to the end of the removal of copper by means of hydrogen sulphide, with the exception that 5 g. of the material should be employed. The filtrate from the copper sulphide contained in a conical flask is boiled until free from hydrogen sulphide, neutralised with sodium carbonate, acidified faintly with hydrochloric acid, after which an excess of finely divided barium carbonate is added and the mixture shaken for 2 hours. The iron and chromium are absorbed completely in the carbonate and removed by filtration. The filtrate and washings are then evaporated to dryness, heated with concentrated sulphuric acid and a little nitric acid to remove chlorides and analysed for manganese as in Method No. 39(a).

### 40. ZINC

#### Extraction procedure

10 g. of the material, cut into small pieces and thoroughly sampled, are digested for 30 minutes with 130 ml. of water and 20 ml. of N-hydrochloric acid in a 250 ml. conical flask immersed in an actively boiling water bath. The extract is filtered by suction through a No. 1 Whatman filter paper and the material well pressed and washed with four portions of 20 ml. of boiling distilled water. The filtrate and washings are cooled and made up to 250 ml.

### Method

100 ml. of the solution are transferred to a 500 ml. conical flask and treated with 2N-ammonium hydroxide solution until just alkaline to methyl red. 10 ml. of 2N-ammonium chloride solution, 25 ml. of N-sodium acetate solution and 6 ml. of N-acetic acid are added and the solution diluted to 190 ml. with distilled water after heating to 70° C. 9 ml. of 2 per cent. oxine in N-acetic acid are added and the solution brought to the boil. The flask, loosely stoppered, is then placed on a steam bath for 30 minutes. The solution is then filtered through a No. 41 or No. 541 Whatman filter paper, the flask washed out with hot water and the precipitate washed a further three times on the filter. The precipitate on the filter and any residue adhering to the sides of the flask are dissolved in 100 ml. of boiling 2N-hydrochloric acid and the solution collected in a 250 ml. long necked flask. After cooling, 1 ml. of methyl red indicator (0.005 per cent. M.R. in 80 per cent. alcohol) is added, and 0.1 N-potassium bromate-bromide solution (2.784 g. potassium bromate and 12 g. potassium bromide per litre) is run in from a burette until the colour of the solution is sulphur yellow. A further 1 ml. of indicator is then added and the process continued until a 1 ml. portion of the indicator is decolourised immediately. This second stage of the titration should not take up more than a few ml. of the potassium bromate-bromide solution. The burette is then adjusted to a convenient mark and the reading noted. The solution is allowed to stand for 2 minutes to ensure complete bromination of the oxine and the excess bromine is then determined by adding 5 ml. of 20 per cent. potassium iodide solution and titrating the liberated iodine with 0.1 N-sodium thiosulphate solution, using a 1 per cent. solution of soluble starch as indicator. The back titration should not exceed 2 ml.

1 ml. of 0.1 N-potassium bromate-bromide solution  $\equiv$  0.0008166 g. zinc.

If the titration with 0.1 N-potassium bromate-bromide solution exceeds 35 ml. the estimation must be repeated using 50 ml. of extract solution instead of 100 ml. This is necessary only when the zinc content is greater than 0.72 per cent.

### 41. LEAD

Incinerate 10 g. of shredded material in a porcelain crucible at low temperature to avoid loss of lead by fusion into the glaze of the crucible or by volatilisation, until all carbonaceous matter is destroyed. Cool and transfer to a 100 ml. beaker. Wash the crucible with small successive quantities of dilute nitric acid (1 volume nitric acid to 2 volumes distilled water) to remove any adherent ash. Make up the solution to approximately 50 ml. with dilute nitric acid and boil for half an hour. Filter through a No. 40 Whatman filter paper into a 600 ml. beaker and wash the beaker and filter paper with hot distilled water. Add 5 ml. of concentrated sulphuric acid (A.R.) to the filtrate and evaporate the solution until sulphuric acid is freely evolved.

Cool, add cautiously about 150 ml. of distilled water and boil the solution for five minutes. Allow to stand overnight at laboratory temperature.

Filter the precipitate through a No. 42 Whatman filter paper and wash several times with 2 per cent. sulphuric acid solution. Boil the paper and precipitate with 20-30 g. of ammonium acetate dissolved in 50 ml. of distilled water in a tall 250 ml. beaker for about half an hour. Filter through a No. 40 Whatman filter paper into a tall 250 ml. beaker and wash the filter paper thoroughly with hot distilled water.

Pass hydrogen sulphide into the filtrate for 10 minutes, stand the beaker on a water bath to coagulate the precipitate of lead sulphide and re-saturate with hydrogen sulphide. Cool and filter through a No. 42 Whatman filter paper and wash with hydrogen sulphide water. Dissolve the precipitate in hot dilute nitric acid and wash the filter paper with hot distilled water. Collect the solution and washings in a 600 ml. beaker and add 5 ml. of concentrated sulphuric

acid (A.R.). Evaporate to fuming, dilute boil and allow to stand overnight as before.

Filter the precipitate on to a G.4 sintered glass crucible (previously washed with hot ammonium acetate solution then hot distilled water, dried at 130° C. and weighed). Wash thoroughly with 2 per cent. sulphuric acid and then finally with methylated spirit. Dry at 130° C. to constant weight.

Extract the contents of the crucible thoroughly with hot ammonium acetate solution and finally wash with hot distilled water. Dry at 130° C. and re-weigh.

Calculate the amount of lead sulphate (the difference between the weight of the crucible before and after extraction with ammonium solution) to percentage metallic lead on the sample.

## 42. PARANITROPHENOL

### Extraction procedure—Solution "A"

A sample, roughly 10 g. of the material to be analysed is cut up into  $\frac{1}{4}$  in. squares. These are mixed well and 2.66 g. (equivalent to 2.50 g. dry cloth) are placed in a glass stoppered 100 ml. conical flask, 50 ml. of N-10 sodium hydroxide are added and the whole weighed.

A glass pear bulb is then substituted temporarily for the stopper and the alkali is just brought to the boil in order to wet out the cotton thoroughly. After cooling, the glass stopper is replaced, the weight adjusted to the original, and the flask is shaken at intervals over about an hour to complete dissolution of the paranitrophenol.

### Solution "B"

A stock reference solution is prepared by dissolving 0.375 g. of paranitrophenol in water containing 1.35 ml. of 2N-sodium hydroxide and making up to 100 ml. This is diluted 100 fold as required to give the reference solution for use in the analysis.

### Method

20 ml. portions of solutions A and B are placed in 25 ml. graduated flasks, neutralised to disappearance of the yellow colour with 2N-acetic acid, and an additional 2 ml. of the acetic acid added to each. The volumes are then made up to 25 ml. and 1 g. of zinc dust is added to each flask, after which they are shaken at intervals over an hour, releasing liberated hydrogen when necessary. The contents are then filtered (Whatman No. 1 paper) and aliquot portions of 1, 2 and 4 ml. are pipetted into 100 ml. boiling tubes, followed by 2.5 ml. of a 1 per cent. solution of sodium orthocresate, water to bring the volume to 45 ml. and then 5 ml. of 2N-acetic acid in the order given. The contents are stirred very thoroughly with a glass rod, and the tubes closed with pear bulbs, are kept overnight to attain full development of the indophenol blue colour.

The reference solutions and as many of the test solutions as come within their ranges are finally compared in a suitable colorimeter.

The technique described covers a paranitrophenol content of the cloth ranging from 0.02 to 0.3 per cent.

## 43. SHIRLAN

5 g. of the material to be analysed shall be cut up into small pieces, well mixed, and portions of 0.5, 0.25, and 0.125 g. are weighed into 3 in.  $\times$   $\frac{3}{4}$  in. specimen tubes.

Eleven lots of 0.5 g. of similar material (i.e. grey or bleached but free from Shirlan) are then weighed similarly to provide references.

5 ml. of 4 per cent. borax saturated with cyclohexanol are added to the material to be analysed; and 5 ml. of solutions of Shirlan in 4 per cent. borax saturated with cyclohexanol, the quantity of Shirlan being varied to give a suitable range, to each of the references. All of the tubes are then stirred intermittently with a glass rod for about an hour. After this 1 ml. from each of the tubes is transferred to a 4 in.  $\times$  1 in. specimen tube; 0.5 ml. of a suspension

of 2:6 dibromquinone chlorimide in 4 per cent. borax saturated with cyclohexanol is added to each, and they are mixed thoroughly. A disc of bleached cloth (diameter less than 1 in.) is then placed in each of the tubes and they are agitated at intervals over about an hour. The discs are then removed, washed gently in a dilute solution of borax, transferred to a white tile and covered with a glass plate. The Shirilan content is estimated by comparing the depth of colour of the disc from the sample that is being analysed with those of the discs from the reference.

With 0.5 g. of material, 5 ml. borax solution, 1 ml. of extract and 0.5 ml. of the dibromquinone chlorimide suspension, the procedure is sensitive to within 10 per cent. for Shirilan contents up to 0.05 per cent. Larger contents of Shirilan may be dealt with by taking a smaller quantity of the sample for analysis and/or by using more than 5 ml. of the borax solution for extraction.

For most purposes the range of solutions of Shirilan used to treat the controls is as follows:—0.005, 0.0045, 0.004, 0.0035, 0.003, 0.0025, 0.002, 0.0015, 0.001, 0.0005, 0.0002 per cent.

These correspond to Shirilan contents of cloth ranging from 0.05 per cent. down to 0.002 per cent.

In order to obtain satisfactory results it is necessary to reduce the particle size of the D.Q.C. by grinding with a little of the borax-cyclohexanol solution.

#### 44. PENTACHLORPHENOL

##### General

It has been found that pentachlorophenol can be removed completely from cotton by means of a solution of borax, and that in order to avoid so far as possible, interference with the colour of the copper derivative, it is essential that the pentachlorophenol should be distilled in steam prior to analysis. The accuracy of the two methods is reasonable ( $\pm 5$  per cent.) and they have been applied satisfactorily to the analysis of a number of undyed and variously dyed cotton yarns and fabrics, and to paper proofed with pentachlorophenol.

##### Preliminary separation

The yarn or fabric (5 g.) previously cut into small pieces, is placed in a 300 ml. round-bottomed short-necked flask and treated with 100 ml. of a saturated solution of borax, using a filter pump to ensure thorough wetting of the material. The flask is then placed in a steam bath and the contents are maintained at about 50° C. for 15 minutes, with frequent shaking, after which the residual cotton is collected in a Buchner funnel, and washed repeatedly with a dilute solution of borax. The extract and washings are transferred quantitatively to a 500 ml. long-necked flask fitted with a spray trap and a vertical double-surfaced condenser, acidified with hydrochloric acid, diluted to about 300 ml. and distilled until 200 mls. have passed over, the distillate being collected in a separating funnel.

##### Method

The distillate is shaken with three successive portions (total 30 ml.) of chloroform, using the first to dissolve any adhering solid from the condenser. The combined extracts are shaken thoroughly with 50 ml. of distilled water and 2 ml. of a 3 per cent. solution of copper sulphate ( $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ) in a 40 per cent. aqueous solution of pyridine. The chloroform layer is run off into a 50 ml. measuring flask and the blue aqueous layer shaken with further small amounts of chloroform. The combined extracts are made up to 50 ml. and compared in a suitable colorimeter with an appropriate standard prepared similarly from a 0.2 per cent. solution of pure pentachlorophenol in chloroform.

#### 45. EXTENDED SOLUBILITY TEST

##### General

This test is intended to be applied to materials proofed with organic anti-septic such as paranitrophenol, Shirilan, pentachlorophenol, etc.

### Testing

A 10 gm. sample of the material is cut into pieces approximately half an inch square, which are then placed in a glass tube about 6 in. long and 1 in. in diameter.

This tube (T) is fitted to the continuous syphon apparatus shown in the accompanying sketch.

The Winchester bottle (A) is filled with 2 l. of distilled water (pH 6.7 to 7.3) and syphoning is started by blowing down the air inlet tube at C. The screw clip is adjusted so that 20 drops of water per minute pass from the apparatus.

The 2 litres will thus require 48 hours to run through the material.

### Performance

The amount of organic antiseptic which is removed during the test is determined by estimating the concentration on the material before and after extraction with distilled water. The quantity of antiseptic removed must not be so great as seriously to interfere with the proofing on the material, which before and after extraction, must be subjected to test No. 46(a).

Fig. 5

## 46. PERFORMANCE TESTS FOR PROOFINGS AGAINST ATTACK BY MICRO-ORGANISMS.

### Foreword

Conformity with a chemical specification does not necessarily mean that the material is proofed against attack by micro-organisms. It is therefore recommended that the chemical estimations be supplemented by a simple qualitative mycological test.

The first of the following tests is intended for application to materials which, under service conditions, are unlikely to come into prolonged contact with soil.

In some instances, however (e.g. sand bags and the valances of tents), the material is liable to attack by both airborne and soil micro-organisms. It is recommended, therefore, that in those cases where the fabrics will, under service conditions, come into prolonged and intimate contact with soil, a microbiological test, in which the effectiveness of the proof against both these forms of attack can be judged, should be prescribed by the specification.

These tests shall be carried out on both leached and unleached material. In the case of organic antiseptics, the leached material is that which has undergone the extended solubility test, whilst in the case of inorganic proofing agents leached material is that which has undergone some form of weathering or accelerated weathering test.

### (a) Test for the Effectiveness of a Proof against Air-borne Microbiological attack

At least two samples (approximately 2 x 2 inches each) of the proofed fabric, together with two samples of untreated fabric, are placed in Petri dishes, and each sprayed with 5 ml. of an aqueous suspension of cellulose-decomposing fungal spores taken from a mixed culture which should contain the following species: *Penicillia*, *Aspergilli* (e.g. *Aspergillus fumigatus*, and *Aspergillus glaucus*), *Cladosporium herbarum*, *Rhizopus nigricans*, *Memnoniella echinala*, *Chaetomium globosum* and *Metarrhizium anisoplia*.

The inoculated samples in the Petri dishes are placed above water in a desiccator, the tap of which is left open, and the desiccator is then stored at 25°-30° C.

If, after 21 days' incubation, the untreated material is covered with fungi, whilst the treated material is completely unaffected, the proof can be considered satisfactory.

(b) **Test for the Effectiveness of a Proof against both Air-borne Microbiological attack and Soil Bacterial attack**

A thin aqueous sludge of a mixture of 2 parts unsterilised soil and one part horse dung is prepared, and the surfaces of Berkfeld filter candles (preferably at least  $6 \times 2$  inches) are impregnated by immersing the candles in the sludge and drawing the liquor through the candles by means of a suction pump. A thin film of inoculum rich in both air-borne micro-organisms and soil bacteria is thereby obtained. Strips of the proofed material are wound round the filter candles which are then fixed in glass jackets and incubated at  $25^{\circ}\text{C}$ . and 92-95 per cent. R.H. for 21 days. Control samples of untreated fabric are tested in a similar manner. After 21 days, the treated sample must be free from fungoid growth. The samples are carefully unwound, washed in running cold water, air-dried, and conditioned in the standard atmosphere for 24 hours. They are then tested for tensile strength. The untreated control samples shall have lost at least 90 per cent. of their initial tensile strength. The loss in tensile strength of the proofed samples not be more than 10 per cent. of its initial value.

NOTES.—This test has the following advantages over a soil burial test:—

It gives more reproducible results.

It more nearly reproduces service conditions in that the outer surface of the fabric is exposed to the air, whilst the inner surface is in close contact with a rich inoculum of soil bacteria.

Unlike the soil burial test, it enables visual results of microbiological attack to be observed.

#### 47. PERFORMANCE TESTS FOR FLAME-PROOFING AND SMOULDER-PROOFING

##### Apparatus

It is strongly recommended that the apparatus for these tests shall conform in its essential features to the following description:—

(1) The platform for the test specimens shall consist of a frame of wood or metal on which are mounted a series of nichrome wires 28 s.w.g. at 1 in. centres, to form a grid for supporting the fabric throughout its length. The frame is graduated in inches along its front edge to facilitate reading of results, the graduations proceeding from the third wire (from the bottom), which is marked zero. The frame shall have an internal width of  $6\frac{1}{2}$  ins., and shall be sufficiently long to accommodate 21 wires in all.

(2) The baseboard on which the specimen platform is suitably mounted, shall be provided with sides and back of ample height, but no front or top. The whole is finished in matt black.

(3) The igniting cup shall be of iron, steel or copper, about  $\frac{1}{2}$  in. thick, and shall be  $\frac{1}{8}$  in. external diameter and  $\frac{3}{32}$  in. high. The cup shall be mounted on cork or other material of low thermal conductivity.

The sketch illustrates the above features, and shows the specimen platform hinged to the base and supported at an angle of  $45^{\circ}$  by a movable arm. It can thus be lowered for easier attachment and removal of the test specimens, and can also be adjusted to other angles of slope if required, by the provision of suitable additional supports, as the smaller one shown in the sketch.

The ignition cup is shown mounted on cork on the head of a screwing arrangement so that its height can be adjusted.

##### Testing Procedure

Specimens of fabric 24 in. long shall be prepared and conditioned as described on page 2.

Fabric up to 6 in. wide shall be tested whole width.

For fabric wider than this, 6 in. strips shall be prepared.

The test pieces are fixed centrally on the specimen platform and secured at top and bottom by means of drawing pins or other suitable means.

Only one specimen of fabric shall be tested at a time irrespective of width.

In the absence of specific instructions to the contrary it is recommended that all tests shall be carried out with the fabric platform at an angle of  $45^\circ$ , and with the ignition cup placed at a vertical distance of 1 in. below the centre of the third (zero) wire.

Fig. 6. Flame-proof and Smoulder-proof Apparatus

A—Specimen platform supported at an angle of  $45^\circ$ . B—Nichrome wires 28 s.w.g. at 1" centres. C—Movable support. D—Extra support if special angle of slope is required. E—Zero mark, F—Ignition cup on screw head.

For each test 0.3 ml. of absolute alcohol shall be poured into the cup from a suitable pipette or burette. The cup is then immediately placed in position and the alcohol ignited by means of a small (bead) gas, or oil jet, or by other suitable small source of heat, which is removed as soon as the alcohol is ignited.

During testing, draughts are excluded, if necessary, by a glass shield placed in front of the apparatus.

The greatest possible accuracy in assessing the results shall be ensured by carrying out the tests in reasonably subdued light, although a dark room is not essential if the apparatus has a good black finish.

An interval of  $2\frac{1}{2}$  minutes shall be allowed to elapse between each test.

Before testing, 0.3 ml. of absolute alcohol shall be burnt in the ignition cup and an interval of  $2\frac{1}{2}$  minutes allowed afterwards, before commencing the first test.

#### Definitions

A material is *flame-proof* when it does not continue to flame after the source of heat is withdrawn.

A material is *smoulder-proof* when it does not continue to smoulder after the flame has died out.

#### Performance

**Flame-proof.** The material specification shall prescribe the maximum permissible time (if any) for continuance of flame, after the source of heat has been removed; and may also prescribe permissible limits (if any) for the extent of scorching or charring.

**Smoulder-proof.** The material specification shall prescribe the maximum permissible time (if any) for continuance of glow after the disappearance of the flame.

## Part IV

### COLOUR FASTNESS TESTS

#### 48. FASTNESS TO LIGHT

The method described in British Standard Specification No. 1006, 1942, shall be used.

NOTE.—It is considered essential that the appropriate Standard or Standards should be exposed with each test.

#### 49. FASTNESS TO WASHING

The tests and machine recommended in the report of the Fastness Committee of the Society of Dyers and Colourists, 1934, page 35, shall be used, with the following modifications:—

(1) The materials under test shall be sewn to a piece of white unmercerised cotton limbric or cambric, 4 × 4 in. (10 × 10 cm.) so as to cover the whole area.

(2) The volume of the test liquor shall be 250 ml. in all cases.

(3) The dyed Standards prescribed in the above report (page 36) have not proved adequate, and cannot now be recommended.

The tests shall be carried out against a portion of the "Sealed Sample."

NOTE.—It must be recognised that many materials coming within the category of narrow fabrics are not washed in practice. It is therefore recommended that the above washing tests be included only in those specifications where washing fastness is an important property of the material.

#### 50. FASTNESS TO BLEEDING AND MARKING OFF

The general method is as follows:—

A test piece about 2 in. (5 cm.) long, covered on one side with a piece of white unmercerised cotton fabric, and on the other side with a white woollen fabric of the same dimensions, shall be placed on the bottom of a flat glass or porcelain dish about 4 ins. (10 cm.) in diameter, with the white cotton fabric uppermost.

The dish shall then be flooded with test liquor without disturbing the assembled materials. After allowing to soak at room temperature for 15 minutes, the materials shall be covered with a smooth glass plate weighing approximately 50 g. Light and even pressure shall be applied on the plate with three fingers, and the excess liquor poured off.

The materials shall then be treated at the temperature and for the time prescribed below, after which they shall be removed from the dish and allowed to dry at room temperature without separation.

When dry, the test piece shall be examined for loss in depth and change in shade, and the white materials for staining.

This general method shall be used with the corresponding modifications when testing for fastness to the following agencies:—

##### 1. Cold Water (Rain)

The test liquor shall be distilled water at 20°-25° C. The duration of treatment shall be 24 hours.

##### 2. Water at Body Temperature

The test liquor shall be distilled water at 37° C. The duration of treatment shall be 4 hours.

##### 3. Perspiration

The test liquors shall be those prescribed in the report of the Fastness Committee of the Society of Dyers and Colourists, 1934, page 27, and the tests shall

be carried out with both the acid and the alkaline perspiration liquors. The temperature of treatment shall be 37° C. and the duration of treatment shall be 4 hours.

NOTE.—All bleeding and marking off tests shall also be carried out against a portion of the "Sealed Sample."

#### 51. FASTNESS TO DECONTAMINATION

The test piece shall be kept immersed in 50 times its own weight of boiling distilled water for 3 hours, and after drying, it shall be examined for loss in depth and change in shade.

NOTE.—The test shall also be carried out against a portion of the "Sealed Sample."

#### 52. FASTNESS TO RUBBING

A test piece about 5 in. (13 cm.) long shall be secured without tension to a flat smooth wooden surface, and strongly rubbed 10 times to and fro over a distance of 4 in. (10 cm.) with a white cotton cambric wrapped round the forefinger.

##### 1. Dry Test

The white cotton cambric shall be used dry.

##### 2. Wet Test

The white cotton cambric shall be wetted, and then squeezed so as to contain approximately its own weight of water.

NOTE.—All rubbing tests shall also be carried out against a portion of the "Sealed Sample."

### CLOTH STRENGTH TESTING—IX

#### EXAMPLES OF INERTIA ERROR IN TEST RESULTS FROM PENDULUM BALANCE TENSILE TESTING MACHINES

By A. W. BAYES

#### INTRODUCTION

This paper describes further work on one of the errors in cloth strength testing. The waviness of load-extension curves drawn by pendulum balance strength testing machines is well-known. Shorter & Hall<sup>1</sup> and Peirce<sup>2</sup> have suggested that the errors associated with this waviness do not attain serious proportions in practice, but their work was confined to single-thread andlea testers. Cloth testing machines of the pendulum balance type have usually much heavier pendulum systems and a faster rate of traverse, and the test specimens are usually much shorter. Paper IV by Martindale & Woods in this series<sup>3</sup> extends the analysis made by Shorter & Hall and shows that serious errors due to the inertia error of the pendulum system are to be expected under certain conditions, namely, with normal Goodbrand machines with 18 inches per minute rate of traverse, testing linen or cotton in 7 inch specimens. The largest errors occur with the weakest specimens and errors are quoted ranging from 30 to 49 per cent. for linen specimens and from 15 to 20 per cent. for cotton specimens. These are estimates from theory of the maximum possible inertia errors and the authors point out that the average errors in practice may be smaller due to non-observance of Hooke's law and to positive and negative errors cancelling.

The reports of various researches explain that testing machine conditions were chosen in which the pendulum jerks had died away before the break, but in others it is obvious that conditions liable to serious inertia errors had been used. In routine testing, machines are used for a wide range of fabrics and some tests are done in which the specimens break after only one or two jerks of the pendulum. The inertia error may, therefore, be important in practice and the present paper presents some evidence of this.

Peirce, Turner, Matthews & Barr have discussed the effect of specimen dimensions on the tested strength of yarns and fabrics. It has been shown by "the weakest link" theory<sup>4</sup> that long specimens must tend to be weaker than short ones and that the strength per unit width is likely to fall as the width of specimen is increased, but it has been suggested<sup>5</sup> that very narrow fabric specimens may be less strong comparatively, and<sup>6</sup> that in some circumstances, if a wide enough range of widths of test specimen could be used, with continuously increasing width, the strength might be expected to increase, decrease, increase and again decrease. Little experimental evidence was put forward in support of these last two suggestions. The weakening of very narrow specimens could occur only once in a series of various widths and the alternate increasing and decreasing is said to require a wide range of widths. No one seems to have suggested that large increases and decreases in strength, occurring between quite small changes in width, could be due to the dimensions of the test specimens.

The jerky movement of the pendulum can be observed easily enough without an autographic recorder. The indicating pointer can be seen to hesitate, and the number of jerks before the break can be counted. On autographic traces the jerks appear with great regularity. It has been shown that these jerks correspond with the theoretical inertia error waves. The object of the present paper is to examine breaking load data for evidence of variations in accordance with the spacing and violence of the jerks. It is assumed that variations in strength per unit width, occurring more or less regularly, at about the spacing, and of about the same magnitude, as would be predicted from Martindale & Woods's formulæ, are, in fact, due to those inertia errors which they analysed. It would be possible to change the spacing of the jerks or waves by altering the traverse speed, or the extensibility of the material tested, or the characteristics of the pendulum, and so to demonstrate whether or not the jerks followed the theory. Alternatively, a variety of materials and testing conditions could be used. The second alternative covers the various machines and materials of practical interest, and is, therefore, to be preferred for the present purpose.

Theory has shown that at a particular jaw speed a pendulum should follow a regularly repeating cycle of acceleration and deceleration. Experiments with weights<sup>7</sup> have shown that the cycles occur, and are associated with inertia errors in the recorded load. Textile specimens introduce variations by changes in extensibility, which affect the head jaw speed, and changes in strength which affect the point in the pendulum cycle at which the specimens break. When the specimens break within the second or third cycle normal variations in extensibility and strength are not likely to mask the inertia effect, but as the number of cycles increases variations in extensibility may mask the effect completely and variations in strength may complicate the analysis. In such series the effect may show up as a cyclic variation in apparent variability of the strength rather than in cyclic variations in mean strength.

Two sets of published data have been found suitable for the present study. The paper then proceeds to experiments designed specially to test the inertia error. Estimates of the period and magnitude of the inertia error were made from the testing machine particulars and the data were subjected to statistical analysis. In all the experiments the normal variability of the material makes it difficult to obtain obvious proof of the error and some of the experiments and analysis may appear somewhat inconclusive, but it is believed that, taken together, they form a considerable body of evidence in support of the conclusions of the theoretical analysis.

The practical question to be answered is: given a particular fabric and set of testing conditions, what error is being introduced by the machine. To answer this three experimental methods may be employed:

- (a) The starting position of the pendulum may be advanced a small amount at a time from zero and the mean strengths and the standard deviation for each starting point compared,
- (b) the strength of the specimen may be varied in small increments, e.g. by varying the width of the specimen; then the variation in mean strength per thread, or per unit of width, should show the extent of the inertia error.
- (c) The specimen width and length may be varied simultaneously.

One difficulty with the second method on normally extensible material is that specimens of any width have practically the same extension at break so that the testing machine behaves differently as the specimen width is changed, and the experimental points are not in fact traversing that error wave in which the normal break occurs. This difficulty may be overcome to some extent by varying the specimen length, between the jaws, and the width together, as in method (c), but as the load-extension curve is not usually straight the speci-

men lengths should be adjusted accordingly. This makes the experiment more complicated and rather less objective.

No doubt the experiments could be simplified by using more regular material such as filament rayon or wire, but the error is most obvious on the less extensible linen and cotton fabrics and, anyway, the aim is to demonstrate the practical importance of the error in normal testing.

#### Examination of some Data published by Matthew, on Linen Fabric

Matthew<sup>8</sup> has described an extensive series of tests on specially woven linen fabrics in which changes in the number of threads per inch in warp and

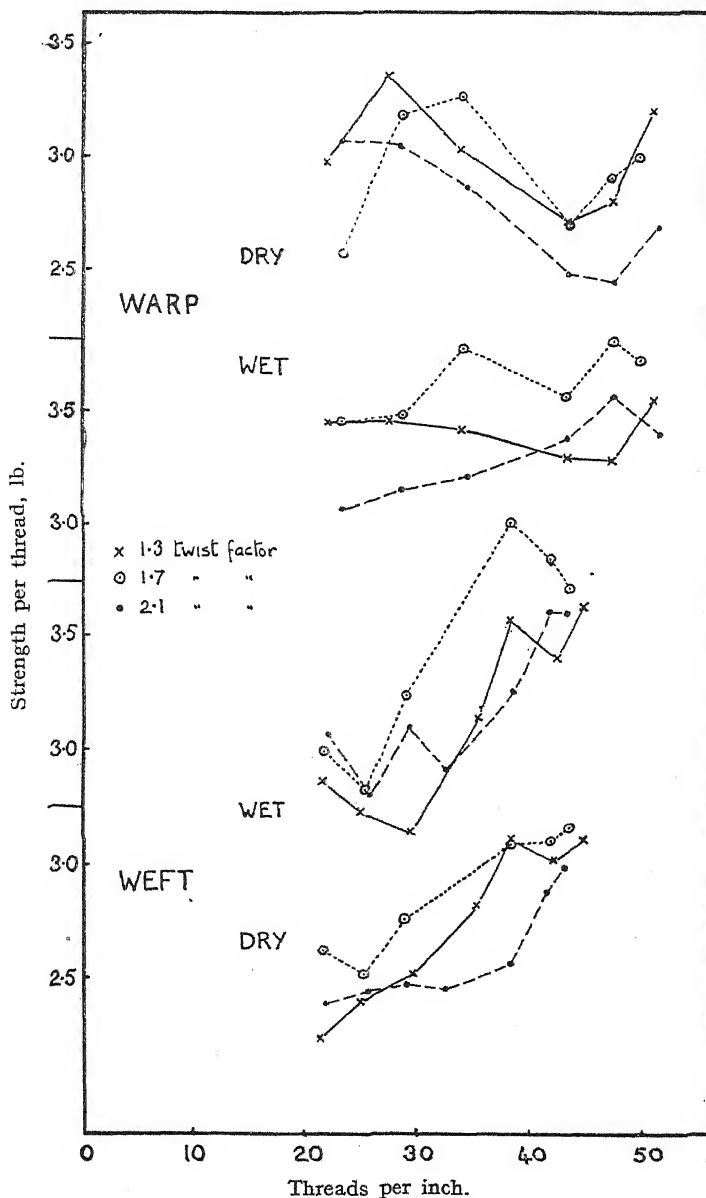

Fig. 1. Variation of strength per thread with the number of threads tested. Linen fabric tested dry and wet (Matthew's data).

weft were made and the effects of these changes were investigated by tensile and other tests. The tensile tests were made on a pendulum balance machine and the author noticed, in one series, an unexpected undulation in the graph when the strength per thread was plotted against the number of threads tested. In his own words: " . . . . . as the number of warp threads is increased the cloth strength per single end increases to a maximum and is followed by a decrease to a minimum, when the strength again increases. The possibility of the effect being due to chance, or errors due to cloth variation, or sampling, appears to be definitely discounted in view of the close similarity in the results from three independent sets of fabrics. So far as the writer is aware there is no previous record of this effect. It is evidently an outstanding feature of the results and therefore it may be presumed that it could be used as a conclusive check on any proposed theories as to the interpretation of the meaning of tensile test results in terms of cloth structure and yarn strength." The data which gave rise to these remarks were obtained on the lines of method (c) so it may be worth while to consider whether the wave noticed by Matthew was due to some curious interaction of cloth structure and yarn strength as he suggests, or to the inertia error of the pendulum system in the testing machine. The testing machine used for these experiments was a Goodbrand horizontal model, 1,000 lb. capacity, with a nominal machine rate of load of 1,100 pounds per inch. The jaw speed was reported as 20 inches per min. The jaws were set 7 inches apart. The specimens ranged in strength from about 100 to 360 lb. From Martindale & Woods's analysis large inertia errors are to be expected under such circumstances. The test material consisted of three series of specially woven and laundered samples of plain linen cloth, made from  $2\frac{1}{2}$  lb. dry spun line, in which the warp ends per inch were varied while the picks were kept approximately constant, and then the picks were varied while the warp ends were kept constant. The changes in thread spacing produced changes in crimp, which in turn produced proportional changes in extension at break. The three series differed in yarn twist factor. All specimens were frayed down to two inches wide. Twelve strips were tested from each sample after conditioning at 75% R.H. and a further twelve were tested after soaking in cold water for 30 minutes. The author has reported mean strengths for dry strips and the percentage increase resulting from wetting, and has plotted the breaking strength per thread for the dry tests against the threads per inch for each twist factor, in his Fig. 8. Of the four sets of graphs plotted therein we are interested in the warp tests with the weft threads per inch kept constant and the weft tests with the warp threads kept constant. The dry warp test graph reproduced at the top of Fig. 1 shows a distinct wave form in all three twist factors, but the dry weft test graph shows a more or less steady rise in strength as the threads per inch are increased. But when the wet strengths are calculated and plotted similarly, the shapes of the graphs are altered; the wet weft now showing what may be part of a wave and the wet warp an upward trend in two of the lines.

The range of strengths from the highest twelve test mean to the lowest for each graph is as follows:

Twist factor of yarn	Range of strength per thread, lb.	
	Warp, dry specimen	Weft, wet specimen
1.3	0.64	1.00
1.7	0.69	1.13
2.1	0.62	0.81
Average range ...	0.65	1.00
Average strength ...	2.93	3.25
Average range % ...	22.2	30.8

Table II of paper IV<sup>3</sup> of this series gives figures for the maximum possible inertia error for linen fabric tested on a machine similar to that used by Matthew, and quotes an error of 35 per cent. at a breaking load of 200 lb., so the maximum possible inertia error is large enough to account for the whole of the range of strength found in these experiments.

An explanation has still to be given for the curious effect of wetting on the shape of the graphs. Matthew pointed out that the effect of wetting was very irregular; increases in strength were recorded ranging from 2.8 to 45.9 per cent. Now the overthrow occurring at the break depends on the value of the breaking load and on the speed of the head jaw, and the speed of the head jaw depends upon the extensibility of the test specimen. It should, therefore, be possible to break specimens at any point in the overthrow cycle by modifying either the strength or the extensibility of the test specimen, but when they are altered together, the effects may cancel, wholly or in part. When the effects oppose one another the wave length of the inertia error cycle will increase and, in a short range of conditions as employed in the present tests, approximately straight line graphs of varying slope will be produced. But when the effects support one another, clearly defined waves are to be expected. It follows from this that a change in the relationship between strength and extension for a particular sample, such as occurs in wetting, may change the graph from a straight line to a wave, and vice versa. If this is the true explanation, the variation in the extent of the strength change, apparently due to wetting, is really due to changes in the inertia error.

#### **Examination of some Data published by Richardson, Bailey and Conrad, on Fibre Bundle Tests**

The simplest extension of the foregoing experiment with weights,<sup>7</sup> is to one employing specimens of negligible length, or of negligible extension. Such very short specimens are used in the Chandler bundle test for cotton hair strength, and a similar technique has been proposed for flat bundles of staple fibre.<sup>9</sup> In both a bundle of fibres of necessarily varying size is broken in special jaws fitted on an ordinary lea tester. The jaws are practically touching, so the headjaw moves almost at the same speed as the pulling jaw, and the varying size of bundle produces breaking loads of varying amount, which, when reduced to strength per fibre unit, should show an inertia error wave similar to that found with weights.

The Chandler bundle test is described in detail in one of the American Society for Testing Materials Standards on Textile Materials.<sup>10</sup> This specification states "a pendulum type testing machine having a capacity of 150 lb. shall be used. The pulling clamp shall have a speed of  $12 \pm \frac{1}{2}$  in./min. . . . Breaking loads shall be tabulated from 50 to 100 lb." The details of the test were investigated at length by Richardson, Bailey and Conrad.<sup>11</sup> They tabulated the bundle strengths of six different cottons measured on about thirty bundles of varying size. Their figures are analysed below in a manner which shows that large systematic overthrow errors are present. Though their machine was of greater capacity than that specified, similar, though possibly smaller, errors are to be expected with the specified capacity.

The technique employed by these workers was as follows: The bundles of fibres were prepared by combing in a standardised manner and each bundle was tightly wrapped with cotton thread in special apparatus. The wrapping proceeded from each end simultaneously towards the middle till the threads touched, then outwards to the ends again. The length of thread used in wrapping was measured and from this length and the thread diameter the "corrected circumference" of the bundles was calculated. The authors give a photograph of their "yarn skein tester adapted for attachment of the special jaws," which appears to be a normal Scott, vertical model, motor driven, pendulum balance, lea tester with the usual ratchet quadrant and pawls on the pendulum lever. The special clamps for gripping the specimen were carried

on extension pieces which appeared to fit directly on the top and bottom hooks of the machine. Apparently the machine capacity was 300 lb. and the jaw speed was 12 inches per minute, although these details are not given specifically.

The paper includes a correlation chart, constructed from a large number of bundle tests, which shows that the density of the bundles decreased as the bundle circumference increased. A regression line is shown on the chart joining the following limits:

Density, gm./c.c.	...	1.61	...	1.31
Circumference, ins.	...	0.095	...	0.170

Having made this point the authors pass on to study the variation of strength with bundle circumference and do not use the regression line further. Whether or not this was the best course for their subsequent analysis our present purpose is better served by applying their regression equation and reducing their breaking loads to breaking stress, in pounds per square inch, at constant bundle density. The data has been re-arranged accordingly by calculating the cross sectional areas from the circumferences, taking the densities from the regression equation, and correcting the breaking stress at the estimated density to breaking stress at a density of 1.55 gm./c.c. (the value quoted by other workers for the density of cotton cellulose).

Assuming that any particular recorded breaking load contains an inertia error of an amount which is unknown, but which is constant for that breaking load, the differences in mean breaking stress between the six samples may be disregarded. The first step in the analysis was, therefore, to express all the breaking stresses as stresses relative to the sample mean. Then the data were collected in groups of similar recorded breaking load, in five pound increments, from 74½ up to 159½ lb. Outside this range the data were too scanty for convenient analysis.\*

Table I gives the arrays obtained in each group. There are 17 groups covering 189 test results. The arrays in Table I show a general curvilinear trend and a variation in array means along the trend, and we wish to test whether the variation of the array means about the trend is statistically significant.

A third order regression line, fitted to the weighted array means by the method of least squares, had the following formula:

$$Y = -1.0716 - 0.032104X + 0.054645X^2 - 0.0064727X^3$$

where Y was the relative breaking stress measured from an origin of 100 and X was the central value of the breaking load group measured in 5 lb. units from an origin of 117 lb. The variance was then analysed into three parts, namely, the variance due to the regression line, the variance between array means and the corresponding regression line values, and the within array variance. The results are given in Table II.

The ratio of the mean square of the deviations of the array means to the residual mean square is 3.73, which is considerably greater than the 1 per cent. point given in the ratio tables for the Z test, so there is statistical confirmation of the reality of the wavy or zigzag variation in bundle strength shown in Table I.

The shape of the general trend is probably due to the use of the original authors' straight regression line for bundle density and circumference. The third order regression line fitted to the array means of Table I curves from 77 lb. to 107 lb. breaking load and then is practically parallel to the breaking load axis up to the limit of the data. Of the bundle densities calculated for

---

\* One low breaking load in lot 4, two low values in lot 6 and twelve high values out of lot 1 were thus left out of the analysis. The effect of this is to make the relative lot means differ from 100 and so to introduce a small between lot mean variance. This has been disregarded in the statistical analysis so the residual mean square in Table II is slightly enlarged.

bundles breaking below 100 lb. half were higher than 1.55 gm./c.c., but it is unlikely that the method of wrapping employed compressed the smaller bundles beyond the normal density of cotton cellulose. The regression line gives a density of 1.55 and over for bundle circumferences of 0.111 in. and below. Evidently the correction is unreliable for this range.\*

\* A.S.T.M. Designation, D414—40T Tentative Methods of Testing Cotton Fibres. Table I. "Tensile Strength for Bundles of Various Circumferences and of Different Observed Breaking Loads," commences at an actual circumference of 0.115 in.

There appear to be four waves between 77 and 157 lb., so if they are due to inertia error the pendulum will have jerked at load intervals of approximately 20 lb. This is the order of interval to be expected on this type and capacity of machine.\*

Inertia error is at least a possible explanation of the variation in breaking stress and, as the average variation appears to amount to about 6 per cent. on the weaker bundles, it seems advisable to modify the test procedure, for instance by a reduction in jaw speed, so that inertia errors are less likely to arise.

Fig. 2. Variation in strength per thread in tests on strips of cloth of varying width.

#### The Effect on the Apparent Strength per Thread of Small Changes in Width in Short Specimens of Cotton Cloth

A simple method of investigating the inertia error wave is to break a long strip of cloth repeatedly, a short length at a time, removing one or two threads from the remainder of the strip after each test. The results, when expressed as strength per thread, would normally be expected to remain constant, or to show a simple trend, but if a pendulum inertia error is present a wave form is to be expected. Weft way strips with all the threads coming from one cop should give the most regular results, but this direction restricts the length of strip available for testing to the width of the cloth.

In an experiment on these lines weft way strips from a plain woven cotton filter cloth were used. The weft was 32s/3 combed Uppers quality. Tests were made on a Scott machine, 400 lb. capacity,  $\frac{1}{2}$  inch between the jaws, 10.4 inches per minute rate of traverse. A load extension chart was drawn for each break and the retaining pawls were in action. Fifteen tests were obtained from each strip. Several strips were tested varying in initial number of threads from 50 down to 15. Fig. 2 reproduces the values obtained for strength per

\* From the text it appears that the machine capacity is 300 lb., and the jaw speed 12 inches per min. From the photograph the testing machine appears to have been made by H. L. Scott. If we may assume that it complied with the A.S.T.M. specification for pendulum type testers, the pendulum deflection at full load was  $45^\circ$ , and the pitch radius of the chain drum in the pendulum head was 11 inches minimum, from which the machine rate of load,  $\mu^0$ , is 340 lb./inch. Then by measurement of the photograph, using an assumed distance between the lea test hooks of 27 inches to fix the scale, the radius of the centre of oscillation of the pendulum is about 18 inches, from which the natural period of oscillation of the pendulum works out at about 1.4 seconds.

The experiments with weights in paper VIII indicated that the period of the error wave approaches one-quarter of the natural period of the pendulum. In the present experiment the head jaw moves at practically the same speed as the pulling jaw, namely 12 in. per minute. The period of the error wave would be expected to be 0.34 secs., in which time the head jaw would move 0.068 inch and the pointer would move through 23.1 lb.

thread plotted against the number of threads in the strip. The results for the three narrowest strips are joined by lines and show a pronounced crest at 6 and 7 threads, but the results of wider strips are more variable and, although there appears to be a second crest at about 20 threads, the third crest is lost in the variability of the material. This test material was chosen for its regularity, so more difficulty is to be expected with more usual, and irregular, cotton fabrics.

The mean strength per thread for the wider specimens is 2.75 lb. The trough at 15 threads averages 7.2 per cent. below this mean, and the crest at 20 threads appears to be rising to about 18 per cent. above the mean.

The maximum inertia error has been calculated for 6, 22 and 36 threads from Martindale and Woods's formula (paper IV, S<sub>31</sub>)<sup>8</sup> taking 11.3 per cent. for the extension at break of the fabric,  $\mu_0 = 454$  lb./in.,  $T = 1.40$  secs.,  $v = 10.4$  in./min. and assuming  $s = s_0$  for these small deflections of the pendulum. The calculation values are:—

Threads broken	...	...	...	6	22	36
Maximum possible inertia error, per cent.	...	61.8	39.2	32.0		
Maximum expected strength per thread, lb....	4.45	3.83	3.63			

A curve has been drawn through these calculated values on Fig. 2. It agrees with the experimental value for 6 threads, but it is much too high for the wider strips.

The load extension charts for strips wider than 15 threads showed an obvious wave at about 38 lb. and the charts for strips wider than 28 threads showed a second wave at about 80 lb. These loads correspond with the first and second troughs in Fig. 2. Some of the curves for the strongest specimens showed a third wave also, but not sufficiently clearly for its position to be measured.

A similar experiment on a horizontal Goodbrand machine with the jaws set  $6\frac{1}{2}$  in. apart gave indications of two waves, but there was considerable variation in the data, and it was clear that a different experimental method was required which would give results more suitable for statistical analysis.

#### The Effect of Changes in the Number of Loops in the Lea Test for Yarn Strength

As in cloth testing it is a simple matter to vary the specimen width a few threads at a time, so in the lea test, although it is customary to break a lea of yarn wrapped in a skein of 80 loops, it is a simple matter to vary the number of loops and so to discover whether the strength per loop remains reasonably constant or whether machine errors introduce inconsistencies. Accordingly a test was carried out on a Goodbrand lea tester as follows:—

The yarn was a commercial 80s/3 super combed and gassed Giza quality with 18 turns per inch in doubling.

The machine details were:—

Capacity, 130 lb.

$v$  = Speed of pulling hook 12 inches/min.

$\mu_0$  = Machine rate of load, 109 lb./inch.

$T$ , Natural period of pendulum, 1.025 secs.

The machine was motor driven through reduction gearing. Multiple retaining pawls held the pendulum in position after the break. Readings of the pointer position were taken to the nearest half pound after the pendulum was held firmly by the pawls. There were five pawls and twelve ratchet teeth for 10 lb. load, so the smallest load change shown by the mechanism was one-sixth of a pound. The pawls appeared to move smoothly. The machine was calibrated by dead weights in small increments before the test and a correction was applied to the lowest readings.

Twenty-four pirns of the yarn from one skip were thoroughly conditioned and then tested repeatedly. Eight pirns were put in the wrap reel together and skeins were made varying in number of loops from 3 to 48 in steps of three loops. The numbers were distributed at random down the pirn. In testing this series it became clear that the steps were too large, so subsequently the test

was repeated on the same pirns at the same controlled humidity and by the same observer taking skeins of 1 and 2, 4 and 5, 7 and 8 loops, etc., up to 23, again at random, down the pirn so obtaining strengths for all loops, from 1 to 24, in steps of one loop. Fig. 3 shows the mean strength per loop for each number of loops. The diagram shows an obvious wave repeating on three loops. The troughs coincide with the first portion of the test so they may be due to some change in testing conditions between the two testing periods instead of to the presumed inertia error. However, the machine pointer hesitated at about 5, 10 and 15 lb. during the tests, which corresponds to the troughs found, and, besides the variation in means, there is a similar cyclic variation in irregularity which is unlikely to have arisen through any

Fig. 3. Variation of strength per loop with the number of loops in the lea test.

unobserved changes in humidity or other testing conditions. It must be concluded, therefore, that the waves are due to some cyclic error in the test, presumably the pendulum inertia error, and not to any change in testing conditions.

The statistical significance of the variation in mean strength per loop was tested for the data of strength per loop from 6 loops to 23 loops, inclusive, 18 loop groups in all for all 24 pirns. The variance was analysed into three sections; between pirns, between loop groups, and residual.

**Analysis of variance, lea test data, units (0.02 lb.)<sup>2</sup>.**

Source	Sum of squares	Degrees of freedom	Mean square
Between loop groups ...	3,997	17	235
Between pirns ...	2,421	23	105
Residual ...	18,823	391	48
Total ...	25,241	431	—

The ratio of the between loop group mean square to the residual is above the 1 per cent. point and the ratio of the between pirn mean square to the residual is between the 1 per cent. and 5 per cent. points, so both sources of variance add significantly to the total and we conclude that the wave is statistically significant.

A further statistical examination was made of the variance within loop groups. The within loop group sum of squares was calculated for each loop group separately and the results are shown plotted on the lower half of Fig. 3. The sum of squares is much higher for six loops than for the others, and there is a cyclic variation repeating on three loops; a high sum of squares coinciding with a low mean strength per loop. The statistical significance of these variations was tested by the  $L_1$  test, using Nayer's tables, by which the ratio of the geometric and the arithmetic means of a series of variances is compared with the ratio for the normal distribution for corresponding degrees of freedom. Various comparisons give the following results:—

	N	k	$L_1$	P
All variances ... ..	24	18	0.820	$P < .01$
All except the variance for 6 loops ... ..	24	17	0.859	$P < .01$
All six crests ... ..	24	6	0.886	$P$ about .01
Five crests excluding the variance for 6 loops ... ..	24	5	0.947	$P > .05$
All troughs ... ..	24	12	0.959	$P > .05$

Evidently, even when the high variance for six loops is omitted, the variation in variance is statistically significant. There is also a real variation between the crest values, though its statistical significance is due to the high value for six loops.

It may be argued that as the number of loops is increased the breaking load variance should fall, although, because the loops are formed from a continuous length of yarn and are not gripped at the hooks, a simple proportional relationship is not to be expected. There is a trend towards lower variances with higher numbers of loops, both with the figures for crests and for troughs, but the change is small compared with the cyclic variation and is not statistically significant so, though the reality of the trend might be proved by more extensive tests, there is no justification for weighting the present data in the analysis of variance.

It is doubtful if either crest or trough values of the variance may be taken as true measures of the yarn variability as the inertia error is likely to cause abnormally regular breaks at one point, and abnormally irregular breaks at another. There is, therefore, this further objection to high speeds of traverse on pendulum type machines, that the standard deviation of the results is biased.

The experimental wave has been compared with the theoretical maximum possible inertia error as for the previous example, taking the effective extension at break of the yarn, from separate measurements, as 3.0 per cent.\* and the mean strength per loop as 1.68 lb.

Loops broken ... ..	6	13	20
Calculated mean breaking load, lb. ... ..	10.1	21.8	30.6
Maximum possible inertia error, per cent. ... ..	3.9	3.6	3.5
Maximum expected strength, per loop lb. ... ..	1.745	1.741	1.738

The curve of the theoretical maximum strength per loop is shown in Fig. 3, and comes rather above the mean values, but the experimental wave extends well below the mean also, so that in the neighbourhood of 20 loops, for instance, the range of strength is about  $5\frac{1}{2}$  per cent. and, for smaller numbers, the range approaches twice the calculated value. This may be because the formula of Martindale and Woods gives the overthrow only, and not the low values due to accelerating the pendulum.

This experiment investigates the lea test at the low end of the dial only, and inertia error waves are demonstrated only for specimens of a quarter of a lea and less. Further, the material is unusually regular and inextensible. It

\*NOTE.—The effective extension is the extension measured on the latter part of the load extension curve. The load extension chart for this yarn showed the usual rapid initial extension followed by a straight line relationship between load and extension up to the break. The slope of the straight portion was equivalent to 3.0 per cent. extension from zero to breaking load. It has been assumed in the present calculations that the effect of the early, rapid extension is negligible.

is quite likely, therefore, that smaller inertia errors are to be expected in normal testing practice, but, on the other hand, the error waves are shown to persist through at least seven cycles, so there are evidently some circumstances in which the effect is not damped by the test specimen and in which the whole extent of the calculated error may be found in practice.

Fig. 4. Strength of weft way strips of Florentine drill with the width and length varied simultaneously.

#### The Effect of Simultaneous Variation in Specimen Width and Length of Cloth Strips

As explained in the introduction, the testing conditions round about the break of a particular size and type of specimen can be traversed by simultaneous adjustment of both specimen width and length. This has been done with weft way strips of a Florentine drill tested on a horizontal Goodbrand machine.

The weft was 22s/2 American cotton 55 picks per inch.

The machine details were:—

Capacity 700 lb.

$v$  speed of pulling jaw 18 inches/min.

$\mu_0$  machine rate of load 638 lb./inch.

$T$ , natural period of pendulum 1.25 secs.

The machine was motor driven through reduction gearing. Multiple retaining pawls held the pendulum in position after the break. The machine pointer pushed before it a light wire pointer pivoted loosely on the main pointer pivot. The position of the wire pointer after the break was read. The machine pointer usually fell back a pound or two after the break as the pawls engaged in the ratchet quadrant. The wire was not seen to jerk forward when the specimens broke.

The cloth was first cut into cop widths and then test specimens were prepared from five of them. From each cop width strips were cut twice the length of the specimens and frayed down to the number of threads required. This provided two tests from every strip and a complete series of tests from each cop. Preliminary tests had shown where the pointer hesitated so the specimens were arranged to give more results at this place. Load-extension diagrams had also shown the customary rapid initial extension, followed by a straight line relationship. From a typical curve, from which  $E=0.00625$

inches/lb., specimen lengths were calculated which would give extensions approximately proportional to the breaking load for each strip width. The strip dimensions tested were:—

Number of picks ... 20 25 30 33 36 39 42 45 48 51 55 60

Distance between  
jaws, inches ... 3.7 4.3 4.9 5.2 5.6 5.9 6.3 6.6 7.0 7.3 7.8 8.4

Fig. 4 shows the individual results of the test with the breaking loads plotted against the specimen width and length. The results obviously follow a wavy line similar to that found on load-extension curves and demonstrate that it is possible to traverse such a line with actual breaking load results.

The movement of the pointer was watched closely during the tests. It was an easy matter to note, approximately, the part of the scale at which the pointer slowed down. The apparent pauses occurred at 30 to 38 lb. and at 71 to 77 lb. The latter does not quite agree with the experimental curve so it seems that the specimen length adjustment had not been quite accurate, but this does not spoil the validity of the experiment.

The data, reduced to strength per thread, have been analysed statistically by the analysis of variance and the  $L_1$  test, which prove that the wave is statistically significant and that the data are significantly more regular for the high strength per thread means (36, 39 and 42 pick strips) than for the low strength per thread means.

$L_1 = 0.675$ .

(from Nayer's table for  $k=12$  and  $N=10$ ,  $L_1=0.789$  lies on the 1% level of significance).

Much the larger part of the variation in variance appears to be associated with the variation in means, but there is a trend also, in which the variance falls as the strip width increases, as would be expected from statistical theory.

Martindale and Woods's formula has been used, as before in this paper, to estimate the maximum possible inertia error. Taking the grand mean strength per pick, of 1.796 lb., an effective extension of 8.3 per cent. and a strip 36 picks wide, 5.6 in. between the jaws, the maximum strength per pick works out at 2.014 lb. This is slightly more than the experimental result, but the succeeding minimum strength, at 55 picks, is 4.8 per cent. below the mean, and the range from crest to trough in the mean values is greater than the calculated inertia error.

A second test was made on specimens from the same piece of cloth, but using wider strips and a different load-extension gradient ( $E=0.00408$  inches/lb.) which, it was thought, would make the results fit the observed pauses more closely. One set of samples was prepared from each of ten cops. The strip dimensions tested were:—

Number of picks ... 51 55 60 63 66 69 72 75 78 81 85 90

Distance between  
jaws, inches ... 4.8 5.1 5.4 5.6 5.8 6.0 6.2 6.4 6.6 6.8 7.1 7.4

The mean strengths per thread in the first experiment appeared to follow a saw-tooth wave like that obtained in the earlier experiment with weights,

and the means for the narrower strips in the second experiment similar, followed a straight line down to a minimum, but the means for the three widest strips did not show the expected rise. The analysis of variance showed that the significance of the between strip widths variance was just below the 5 per cent level, and the value of  $L_1$  was not significantly different from unity. Omission of the three widest strips from the analysis brought the ratio of  $t_1$  between strip width variance up to the 1 per cent. level, but the results remain much less spectacular than the first experiment and the value of  $L_1$  was still not significantly different from unity. It seems likely that the chief reason for this different result is an unsuitable choice of specimen lengths. This view is supported by the results of further tests in which specimens of the same width as those which gave the highest and lowest results in the second experiment were tested at other specimen lengths. Specimens 51 picks wide and 4.8 inches between the jaws, gave the maximum strength in the second experiment, but in further tests, at jaw spacings of 2.9, 3.6, 4.2 and 4.4 inches, maximum strength was reached at about 3.6 inches. Similarly 69 pick strips 6.0 inches between the jaws gave the minimum strength in the second experiment, but with this strip width further tests at jaw spacings of 5.1, 5.7, 6.3 and 6 inches, indicated that the lowest strength was to be expected at the original spacing of 6.0 inches between the jaws. It seems likely, therefore, that a steeper gradient, more nearly equal to that used in the first experiment would have given a more obvious wave.

**Analysis of Variance. Florentine weft, 2nd experiment, strength per thread units (1 lb.)<sup>2</sup>**

Between strip width ...	0.1635	11	0.01305
Between cops ...	0.3015	9	0.03339
Residual ...	0.6687	99	0.00675
Total ...	1.1337	119	—

**Analysis of Variance. Florentine weft 2nd experiment, excluding widest strip**

Source	Sum of squares	Degrees of freedom	Mean square
Between strip width ...	0.1300	8	0.01625
Between cops ...	0.1777	9	0.01974
Residual ...	0.3991	72	0.00554
Total ...	0.7068	89	—

It would be expected from general considerations that a maximum inertia error could be obtained at a particular point only by a nice adjustment of the variables, and so this method of simultaneous variation of width and length can be effective only when the extension characteristics of the test material are well known.

**The Effect on the Apparent Strength of Cloth Strips of Varying the Starting Position of the Pendulum**

In the earlier experiments with weights it was shown that the inertia error wave could be traversed by advancing the starting position of the pendulum. The experiment now to be described applies the same idea to tests with fabric strips. The advantage of this method of investigation is that the strip dimensions are constant throughout the test, which eliminates one source of variation in the group variances, so showing up more clearly the effect of inertia error on variance.

A comparison of parallel routine tests from two laboratories had shown considerable discrepancies both in means and in standard deviations and, as calculations showed that considerable inertia errors were to be expected in both sets of results, a special investigation was undertaken on one machine. The particulars were:—

Testing machine: Scott 400 lb. capacity, 10.4 inches/minute rate of traverse, machine rate of load,  $\mu_0$ , 454 lb./min., natural period of the pendulum, T, 1.40 secs.

Fabric: Weft strips 1 in. wide, 4 in. between the jaws. Three shaft drill. Five cop widths of cloth were taken from the same cutting and from each cop width five strips were cut the full width of the cloth and frayed down to 50 picks wide. Then, after thorough conditioning, each strip was tested eight times along its length, each time with the pendulum starting from a different place. The starting point for successive tests was chosen at random for each test. The results were analysed statistically for each cop width separately and then, as the between-strip variance was significantly greater than the residual for each cop the results were regrouped into five classes in which the strip means were more nearly equal. The data in these classes were analysed again separately for each class as before.

Analysis of Variance. Drill weft, units ( $\frac{1}{2}$  lb.)<sup>2</sup>

Significance from ratio tables by Mahalanobis

\* barely on the 5 per cent. point of significance

\*\* between the 5 per cent. and 1 per cent. points

\*\*\* on the 1 per cent. point and over.

The analysis shows that the rearrangement of the strips improves the comparison, eliminating much of the between strip variation and improving the significance of the between-pendulum-settings variance, but even without rearrangement the between-pendulum-settings variance is significantly different from the residual.

The variance was tested for homogeneity by the  $L_1$  test for which the variance for each pendulum setting in each class of five strips was calculated separately and then these were combined for all five classes, yielding eight variances based on twenty-five tests each. The value of  $L_1$  was 0.8487 which, for  $k=8$  and  $N=25$  lies between the 0.05 and 0.01 levels of significance.

Figure 5 shows the mean values of strength for each pendulum setting in each class, together with the sum of squares for all classes. Classes V, W and X and the variance show an obvious wave, but Y and Z do not. The graph of the mean of all classes is similarly wavy. It is not clear why classes Y and Z have failed to show a wave. The mean curve ranges from a maximum of

71.82 lb. at 6 lb. starting point to 69.46 lb. at 12 lb. starting point; a range of 3.3 per cent. whereas the calculated value of the maximum possible inertia error for the conditions of this test is 15.3 per cent. The range for the largest wave, Class W, is 7.2 per cent., or about half of the calculated value, but the graph of the variances shows that the results are very variable when the mean strength curve reaches both its minimum and its maximum, so it would be unwise to suppose that the error in individual results is never larger than the mean variation found in this experiment, or in Class W. It seems more likely that the full calculated error has occurred in many of the tests, but that the variability of the material has made the waves overlap, so lowering the crest, and raising the trough, and increasing the variability.

Fig. 5. Variation in the apparent strength of weft way strips of 3 shaft drill as the starting position of the pendulum is altered.

## GENERAL DISCUSSION

Two examples from the literature and four special experiments have been employed to demonstrate the practical importance of the inertia error in pendulum type-testing machines. Routine load-extension charts on a wide variety of fabrics show that waves invariably occur at normal jaw speeds. In general, the first wave along a trace is shorter than the remainder, and the more extensible the test piece the shorter the waves tend to be. Repeats of the wave can commonly be followed through five cycles, and even up to seven, but there are some indications that waves of the correct period, but which fail to die away, may be caused by friction in the head jaw. Such waves can be demonstrated by deflecting the test specimen round guide pulleys arranged between the machine jaws. Then, as the specimen extends under load, the pulleys slowly rotate, but the friction in their journals may be sufficient to make their action jerky, and so to keep the pendulum moving jerkily throughout its traverse. A similar friction effect may be present in the head jaw slides of horizontal machines when they are inadequately lubricated, and, again, quite small burrs on the teeth of the ratchet quadrant are capable of modifying the pendulum movement and regenerating the inertia wave.

Matthew's data appear to cover the second and beginning of the third wave; Richardson, Bailey and Conrad's data appear to trace from the fifth to the tenth wave. In the present tests waves extending to seven repeats were found in the lea test and up to five in a test on cloth. Presumably, the more nearly perfect the elasticity of the material, the more clearly will the waves persist, but when many waves are present small differences in strength or in extensibility between samples will mask the effect of the waves on the average breaking load.

The significant variations in variance, found in addition to the variations in average strength, show that even in these special experiments the variations in average strength do not measure the whole of the calculated inertia error. It does not seem possible to find out how much of the breaking load indicated for a particular strip is inertia error. Real variations in strength merge with variations in the error to produce a general variability which cannot normally be split up. However, the variations in average and variance appear to be broadly in accordance with the theoretical calculations. The crests of the later waves do not always rise to the expected level, but on the other hand the data show negative inertia errors occurring immediately after a pause when the pendulum is being accelerated, and the calculations do not provide for this, so that, in the absence of more precise information, the formula proposed by Martindale and Woods (paper IV S31) can be used to estimate the probable maximum inertia error occurring in individual test results.

The current A.S.T.M. standard for textile testing machines<sup>7</sup> requires that the specimen shall break when the angle which the pendulum makes with the vertical is between 9 and 45°. In practice the pendulum is deflected to 45° at the maximum reading of the machine and the lower limit for specimen breaks is marked at one-fifth of this. Similarly the U.S. Government<sup>8</sup> has fixed a limit at one-tenth of the machine capacity. It seems likely that these limits have been fixed from practical experience of the unreliability of results obtained at small pendulum deflections. Martindale and Woods' formula could be used to estimate more precisely the lower limits of the dial reading which should be employed for particular specimen characteristics. The higher the jaw speed used, the higher the limit of readings should be. It seems impracticable to have speed changes from cloth to cloth on this type of testing machine. Some Goodbrand machines are already provided with gear boxes giving a speed of  $4\frac{1}{2}$  inches per minute. Much lower speeds than this appear to be indicated by the formula for linen and cotton if the inertia error is to be kept down to  $\frac{1}{2}$  per cent., but these make the test very slow. Bearing in mind the other possibilities of error and the probable effect of averaging, it may be advisable to standardise Goodbrand machines at  $4\frac{1}{2}$  inches per minute rate of

traverse and to prescribe minimum breaking loads for particular types of fibre or particular cloth extensibilities. These minima could be calculated, but it might be sufficient to take them as a multiple of the observed wave length, e.g. ten times the load at the first pause. It would be necessary to increase the width of specimen for weak fabrics to bring their breaking loads up to the calculated minimum. This is already done to some extent; fabrics being tested in widths of 2 in., 4 in. and  $6\frac{1}{2}$  in. Comparisons between different fabrics would be complicated by the variations in strip width, but complications from one source or another seem to be inevitable.

The present tests do not provide an exhaustive examination of the behaviour even of cotton fabrics. They have had to be confined, indeed, to somewhat unusual testing conditions in order to obtain measurable errors and the results must be used with caution. It may be that inertia errors do not account for any large part of the differences experienced between laboratories in tests of warp way strips of heavy drills and ducks, but it is usual to test weft way strips under the same conditions and these, being commonly weaker and less extensible, are more likely to give appreciable inertia errors. The wide variety of fabrics makes it likely that tests are frequently attempted on unsuitable capacities of machines and the use by some British firms of American specifications, built on the vertical Scott machine, introduces strip dimensions smaller than are advisable for the usual Goodbrand machine. Further, as the industrial uses of fabric extend, tests are likely to be made on pendulum type machines designed for other materials. When the testing facilities are not ideal there is a temptation to argue, for instance, that the lower portion of the scale of a heavy capacity machine is sufficiently accurate for routine testing because there appears to be no reason why a small deflection in a pendulum balance device should not be measured accurately. But the difficulty is not with the pendulum regarded as a static weighing device. Luckily the presence of serious errors can be judged easily from the motion of the pointer.

It is to be expected that a particular cloth will give fairly consistent results in repeat tests on one machine, but it does not follow that equivalent results should be expected on a different machine, or that consistent differences will be found between cloths. A specified strength will normally be fixed from experience with a particular set of conditions, but these conditions may give rise to an appreciable overthrow error and the specified figure will then include this error. In the meetings of the Physical Testing Committee of the Institute Standardisation Scheme it has been pointed out that although the strength of a fabric is commonly specified as so many pounds, the figure is to be understood to apply solely to the machine and speed specified, and therefore to include all the errors associated with that machine and speed. It by no means follows that the same strength is to be expected at a different speed, at a different machine capacity, or machine rate of loading, or on a machine differing in the method of applying the load, for example, with a spring loaded machine.

The relative importance of different sources must vary with the conditions. No doubt in some machines the chief errors are due to inadequate maintenance and in others to poor technique. The inertia error is one of many difficulties in fabric testing.

### CONCLUSIONS

(1) Experiments on cotton specimens confirm the reality of cyclic errors corresponding to the inertia errors examined in earlier papers. These affect the mean strength and the standard deviation.

(2) The error cycles or waves persist through several repeats, but the variability of the material makes them difficult to isolate.

(3) The errors are large for relatively weak and inextensible specimens. The jaw speeds in common use on pendulum type machines are too fast. Theory indicates that if the maximum possible inertia error is to be reduced to  $\frac{1}{2}$  per cent., the jaw speed should be reduced for linen and cotton to less

than one twentieth of its present value. This would make testing impracticably slow. As interest is centred chiefly on the average of a set of tests and the inertia error probably varies within such a set, it may be permissible to provide for a higher maximum possible inertia error, of say 2 per cent., and to employ schedules of minimum breaking loads for different types and dimensions of specimen. It is suggested that the speed of  $4\frac{1}{2}$  inches per minute now used on Goodbrand machines in some quarters should be regarded as a maximum for cotton and linen fabrics.

(4) It does not appear to be practicable to apply a correction for the inertia error except, perhaps, to the results of the Chandler bundle test in which the extensibility of the specimen is likely to be so small that the error is independent of the test specimen.

Much of the work reported in this paper has been done by Mr. W. Clegg and Miss B. Wadsworth. The author's thanks are due to them, and also to the Directors of Messrs. Ashton Brothers & Company, Limited, for permission to publish the paper.

## **TENTATIVE TEXTILE STANDARD No. 7, 1942**

### **Specification for a Bundesmann Type Water Repellency Testing Machine**

Tentative Textile Standard No. 7, 1942—"Specification for a Bundesmann Type Water Repellency Testing Machine," published in the *Journal* of the Textile Institute, 1942, 33, S50-S52, has been before the members of the Institute for the required period of ten months. It is proposed, unless any objections are received, to submit this tentative standard to the British Standards Institution for acceptance as a British Standard (Textile). Comments should reach the Acting General Secretary not later than 31st December.

The Method of Test for a Bundesmann Type Water Repellency Testing Machine will form the subject of Tentative Textile Standard No. 8. This will be published at a later date.

## **TENTATIVE TEXTILE STANDARD No. 1a, 1942**

### **Standard Method for Determining Resistance to Shrinkage of Wool Fabrics**

This tentative standard was published in the *Journal* of the Textile Institute, 1942, 33, S41-S48. In the light of further development work the recommendations are now being revised. The technical committee which is dealing with this work will also give consideration to any comments on the published tentative standard which are received not later than 31st December.
